Budgetary Catalyst Proposal for GRE Coal Creek SCR Project

B&V No. 400075.60.1000

CERAM Proposal No. GH190617-1 - Confidential

Dear Mr. Dittus:

With reference to your request for a budgetary quotation from the June 13, 2019 conference call, IBIDEN CERAM, Inc. (CERAM) is pleased to provide Black & Veatch (B&V) with our budgetary proposal for supplying selective catalytic reduction (SCR) catalyst for the Great River Energy (GRE) Coal Creek SCR Project. We have based our catalyst design on the design data e-mailed by B&V on October 9, 2018 and further correspondence provided in both May and June 2019. Our proposal described herein is based on supplying honeycomb catalyst manufactured at our production plant located in Frauental, Austria. Since 1985, CERAM has produced over 180,000 m³ of SCR homogeneous honeycomb and plate type catalyst for over 1,600 applications and is a world leader in the supply of this product. CERAM has proposed using our [REDACTED] pitch honeycomb catalyst for this application due to the high temperature and required specific surface area.

B&V specified that the catalyst would be in a high dust arrangement or immediately downstream of the economizer boiler section. There were no design constraints on the size or number of SCR reactors or catalyst layers required to meet the DeNOx demand (e.g., 69% NOx reduction and 2 ppmvdc ammonia slip for 24,000 hours). The design information indicated the fuel to be North Dakota (ND) lignite. CERAM does not have direct experience with ND lignite, but we have developed a wide portfolio of experience and have mainly focused on "dirty" gas applications. While not every application has the exact same design basis, we do have experience with other lignite and brown coal fired applications using both of our honeycomb and plate catalysts. However, the high levels of sodium oxide (Na₂O) (>4%) in the ash for the ND lignite are not commonly found in sub-bituminous, bituminous and other lignite coals based on our supplied experience. Moreover, the ND coal analysis indicates there are high levels of various other catalyst poisons (arsenic, potassium, etc.) and masking agents (calcium sulfate, etc.) that must be taken into consideration in an SCR catalyst design. Table 1 summarizes our budgetary catalyst design for the project. Additional design details are provided in Attachment A. Table 2 summarizes the scope of supply, delivery, and budgetary pricing regarding this offering.

IBIDEN CERAM, Inc.

Table 1. GRE Coal Creek SCR Catalyst Design Summary ⁽¹⁾		
Catalyst Design:		
Catalyst Pitch / Element Length, mm	[REDACTED] / [REDACTED]	
No. of Reactors / Initial Layers Installed	2 / 3	
Module Arrangement per Layer	13 x 9	
Catalyst Volume/Reactor, m ³	[REDACTED]	
Performance: ^{(2),(3)}	Case 1	Case 2
Inlet NOx, ppmvd act. O ₂	126	60
Outlet NOx, ppmvd act. O ₂	39 (69% reduction)	18.6 (69% reduction)
Initial Pressure Drop, in. w.g.	2.1 (clean) / 2.6 (dirty)	
Initial Ammonia Slip, ppmvd ref. O ₂	2	
Initial SO ₂ to SO ₃ Oxidation Rate, %	5	
Guarantee Life, (hours)	24,000 (or 36 months from delivery); Dependent on Pilot Scale Test Results	
Notes:		
1. Reference Attachment A (CERAM data sheet) for further information.		
2. SO ₂ to SO ₃ oxidation design for ammonia on conditions ($\alpha = 1$).		
3. Guarantees for NOx reduction, ammonia slip, pressure drop and SO ₂ to SO ₃ oxidation for Test A only (reference proposal for further information).		

Table 2 – GRE Coal Creek Catalyst Scope of Supply and Budgetary Pricing	
Scope of Supply: Production Testing and Documentation Catalyst with Steel Module Frames Module-to-Module and Module-to-Reactor Wall Seals 50% of the Frames with 1 Removable Full Size Test Element 20 Replacement Test Elements Cover Grates for Each Module Four Lifting Frames Operation & Maintenance Manuals & Required Performance Curves Catalyst Module, Lifting Frame and Seal Drawings (6 weeks after receipt of order) Protective Crating to the Site Freight to Jobsite (DDP to site; Assume delivery 1 st quarter 2021)	
Budgetary Pricing: (Validity is 60 Days)	
Base Design: [REDACTED] Pitch Catalyst ([REDACTED])	\$6,100,000
Note: (1) CERAM is willing to work with GRE and B&V with regards to payment terms in order to meet the project requirements. We understand that at this point in the project the main commercial driver is the performance guarantees and budgetary catalyst scope of supply pricing.	

Catalyst Deactivation

CERAM's experience with sodium levels greater than 4% has shown that catalyst deactivation would be higher than a typical bituminous or sub-bituminous coal fired application. Figure 1 shows the percentages of sodium from the Falkirk mine based on 5,531 samples. Our catalyst design was based on a maximum sodium percentage of 4% (12% ash). The data indicates that for approximately 27% of the samples the sodium percentage would be greater than 4%. While CERAM does not have direct experience with firing North Dakota lignite, we based our current design on our biomass experience (e.g., wood, switch grass, etc.) where there are also high alkalis, such as potassium and sodium. However, the upper range of sodium shown in the ND lignite data set is outside our operating experience. Therefore, we expect the catalyst deactivation to be accelerated due to the higher levels of sodium (>4%).

Figure 1. Sodium in ash percentages from the Falkirk Pit samples based on 20 year projections provided by GRE/B&V.

CERAM's experience with biomass applications in a high dust arrangement were successful because we were able to take advantage of the lower flame temperature (e.g., less oxidized poisons) with using a bubbling fluidized bed (BFB) boiler and the nature of a BFB where there is available sorbent (e.g., limestone) that can absorb a portion of the catalyst poisons and a large portion of the ash is entrained. Pulverized coal (PC) boilers in a high dust arrangement can lead to an increase in deactivation due to the higher local flame temperature and areas of incomplete combustion that both can lead to a severe increase in oxidized poisons, such as sodium oxide, arsenic trioxide, etc.

Catalyst deactivation due to the high sodium levels will occur based on normal operations from the formation of sodium aerosols and from poisoning that would occur during outages. The effects of sodium in the particulate form can be controlled by maintaining warm and dry conditions on the catalyst at all times during layup conditions of the SCR reactor. However, if there are moist conditions on the catalyst, such as condensation during an outage then the particulate bound sodium will leach into the pore structure of the catalyst where catalyst poisoning will occur. Small aerosol particles will penetrate and neutralize active catalyst sites even in dry conditions; however the effect is much worse when moisture is present. The current catalyst management plan from GRE and B&V would be to replace all of the catalyst every three years due to Coal Creeks expected three year outage cycle. CERAM agrees this would eliminate the effects of deactivation during scheduled outages, since all six levels of catalyst would be replaced, however the forced outages must also be taken into consideration. There must be no moisture in the SCR reactor during layup or when the SCR is isolated for example during an unexpected boiler outage. In this regard, maintaining temperatures greater than or equal to 300 F would be recommended. Prior to short term isolation the catalyst layers should be air purged with dry acid free air to prevent condensation of moisture on the catalyst surface and never isolate the reactor with flue gas. Startups and the time needed to put the SCR in surface would need to be minimized/optimized to reduce the effects of deactivation. Due to the possibility of high sodium concentrations, CERAM would recommend a full SCR bypass system be installed. During lay-up periods the catalyst would need to remain warm and dry perhaps by using an air drying or dehumidification system.

Catalyst Performance Guarantees

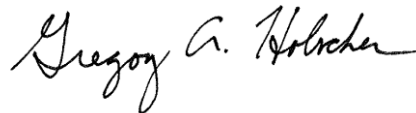

Catalyst deactivates due to the exposure of flue gas. It is known in the industry that catalyst deactivation is a result of the operating conditions and fuels fired, and is independent of catalyst type or manufacturer. The goal of properly designing catalyst is to accurately predict the rate of catalyst deactivation for a given project. Since there is no direct experience in the industry with SCR catalyst installed on a unit firing ND lignite, it is difficult to determine with a high level of certainty what the long term impacts will be on the SCR catalyst. As such, it is very risky and difficult to provide life guarantees for this application until further field testing is performed to fully assess the long term impacts.

Based on the budgetary catalyst design included herein, CERAM would be willing to provide initial (Test A) performance guarantees which would include NO_x reduction, ammonia slip, SO₂ to SO₃ conversion rate, pressure drop and ammonia slip. Additional, data that would be very useful would be to understand the concentrations and particle size distribution of the probable catalyst poisons from firing ND lignite. The most critical information is how the small particles which are present in the flue gas stream will affect the catalyst by either poisoning or fouling mechanisms. CERAM believes that with additional field testing information that catalyst life guarantees could also be provided. The budgetary design presented is for a 24,000 hour or 3 year period to reflect the planned outage schedule at Coal Creek, however CERAM is unable to offer end of life performance guarantees given the potential for high sodium levels without additional field information. CERAM would recommend a pilot test using CERAM's CoPilot[®] Test Reactor, or a similar device to develop long term trends associated with catalyst deactivation.

The pilot test program would involve flue gas exposure of one to several catalyst elements under conditions that would replicate the actual SCR system. CERAM recommends at least 2,000 hours of exposure per catalyst sample. As many as 5,000 hours of exposure would be preferred. Based on participation in such a pilot test program, CERAM would be able to provide 24,000 hour life guarantees for this project. In this situation, CERAM would prefer to work in an “open book” manner to design the catalyst with direct input from B&V and GRE with regards to catalyst design and sizing margin.

We hope this proposal meets your expectations. Please contact John Cochran (john.cochran@ceram-usa.com) or myself (greg.holscher@ceram-usa.com) at 913-239-9896 should you have any questions or need any further information.

Yours sincerely,
IBIDEN CERAM, Inc.

Gregory A. Holscher, Ph.D.
Senior Applications Engineer

SUBJECT: GREAT RIVER ENERGY – REQUEST FOR PROPOSAL

**COAL CREEK STATION UNIT 2 NOxOUT® SNCR SYSTEM
FUEL TECH BUDGETARY PROPOSAL NO. 18-B-064, REVISION 2 – REDACTED**

Dear Ms. Berge:

Fuel Tech, Inc. (FTEK) is pleased to submit our preliminary and budgetary Proposal 18-B-064, Revision 2, to Great River Energy (GRE) for the Coal Creek Station (CCS) Unit 2. The following proposal provides the technical, performance, and commercial details for the FTEK Selective Non-Catalytic Reduction (SNCR) system for CCS Unit 2 located in Underwood, ND.

FTEK's scope includes the design and supply of the SNCR system including reagent storage, forwarding, metering, distribution, and injection equipment including field startup and optimization services. The reagent storage has been sized for thirty (30) days of storage and the system will be controlled via the Plant's Honeywell DCS System.

The process performance provided in this budgetary proposal is based on the furnace mapping information measured during the week of October 22, 2018. We have provided NOx reduction performance for 5 and 10 ppm ammonia slip cases. This revision includes the addition of four (4) additional wall injectors and one (1) 4-pack Distribution Module on Zone 2. There is no change to performance.

FTEK's SNCR reduction system is designed to cover a boiler load range of 185 – 600 MWg (~31 – 100% MCR). If the load range was decreased to 50 – 100% MCR, the Zone 1 Injectors (lowest level in the furnace) may be eliminated. FTEK could investigate the scope, cost, and utility consumption impacts of this change upon request.

We trust the information provided in the Offering meets your needs. In the meantime, please do not hesitate to contact me if there are any questions or comments.

Sincerely,

Dale Pfaff
Regional Sales Manager

1. EXECUTIVE SUMMARY

1.1. Introduction

In response to Great River Energy (GRE) and the Request for Quotation, Fuel Tech, Inc. (FTEK) is providing this preliminary and budgetary Proposal for our NOxOUT® Selective Non-Catalytic NOx Reduction (SNCR) system for the Coal Creek Station Unit 2. FTEK's scope of supply includes the design, supply, and commissioning of our NOx reduction technologies applied to the 600 MWg tangential fired boiler located in Underwood, ND.

1.2. Unit Description

Coal Creek Station Unit 2 is a 600 MWg Combustion Engineering tangential fired boiler with eight corners and a divided furnace. The boiler fires 100% ND lignite coal with a permitted heat input of 6,022 MMBTU/hr. A maximum heat input of 5,971 MMBTU/hr was recorded at full load during the testing period and is used in FTEK's evaluation.

Figure 1 - GRE Coal Creek Unit 2

The Unit has Foster Wheeler Low NOx Combustion System with close coupled over fire air (CCOFA) and separated over fire air (SOFA) systems. The NOx baseline concentration of 0.121 lb/MMBtu used in FTEK's evaluation corresponds to the average emissions measured during the temperature mapping tests performed under full load conditions. For this proposal effort, the SNCR reduction system is designed to cover a load range of 185 – 600 MWg (~31 – 100% MCR). If the load range was decreased to 50 – 100% MCR, the Zone 1 Injectors (lowest level in the furnace) may be eliminated.

1.3. Proposal Summary

FTEK has evaluated our SNCR process at 5 ppm and 10 ppm ammonia slip levels for GRE's consideration. The process design tables are broken down by 1) Wall Injectors only and Wall Injectors plus Multiple Nozzle Lances (MNLs) at 5 ppm slip and, 2) Wall Injectors only and Wall Injectors plus MNLs at 10 ppm ammonia slip. This proposal scope focuses on the 10 ppm ammonia slip scenarios. The NOxOUT SNCR process description and expected NOx reduction performance results of the SNCR system are detailed in Sections 2 and 3, respectively.

The equipment and engineering scope of supply summary is provided in Section 4 of this Proposal. FTEK utilized the urea flow rate at full load for thirty (30) days of 50% aqueous urea storage based on the 10 ppm ammonia slip case. Therefore, FTEK has included four (4) 70,000-gallon FRP tank with a circulation module. The reagent storage tanks include heat pads and insulation while the circulation module includes a pre-fabricated building to be located outdoors near the tank. All other modules must be located indoors for freeze protection.

The FTEK modules will include NEMA 4 junction boxes that will be controlled via the Owner's DCS System. At this writing, our scope of supply is based on our standard equipment specifications and manufacturers. Our scope of supply and drawings are provided in Sections 4 and 5, respectively.

FTEK will provide SAMA Logic diagrams and functional descriptions for programming by others. BOP engineering, air compressors, and water systems required for the SNCR systems shall be provided by others. The scope of supply by others and utility requirements are detailed in Section 6.

The NOxOUT aqueous urea and dilution water specifications are provided in Section 7. FTEK will review the Owner's water sources to help determine the best water source for dilution of the urea for injection. The engineering, equipment fabrication, and delivery milestone schedule has been detailed in Section 8.

The budgetary and preliminary pricing and payment terms are provided in Section 9. FTEK has provided pricing, expected utility demands, and other information based on the following scope definitions:

- Case 1 – Wall Injectors plus MNLs, 10 ppm Ammonia Slip
- Case 2 – Wall Injectors Only, 10 ppm Ammonia Slip

Pricing includes start up and optimization field services with travel and daily expenses included. Should additional mandays be required above and beyond what was specified in the FTEK Offering, Appendix C1, FTEK Field Service Rates, has been included in Section 10. Fuel Tech has based our commercial offering on our Exhibit C3 – FTEK Commercial Terms and Conditions included in Section 11. As always, FTEK will review and negotiate in good faith once the GRE commercial terms and conditions are provided.

FTEK is the world's leading supplier of combustion and post combustion NOx reduction technologies. These include low NOx Burners, over-fire air systems, urea based SNCR, advanced SCR, and the ULTRA Conversion system for SCR reagent feed. Fuel Tech's commercial experience includes over (108) LNB and OFA systems, (650+) NOxOUT® SNCR/advanced SCR systems, (132) ULTRA® Systems, and 50,000 MW of SCR experience.

FTEK has engineered SNCR systems for a variety of boiler configurations, loads, and process requirements. Our experience encompasses unique challenges including large units with difficult boiler geometry and high temperature furnace conditions, fuel variations and blends, wide operating load ranges, and non-optimal injection locations, all while providing our customers with the maximum, repeatable, and long-term NOx reduction performance expectations and guarantees. A few examples of FTEK's commercial and confidential SNCR experience on large, tangentially fired, coal boilers with low NOx baselines include:

- Confidential Client Names REDACTED

FTEK has more installed SNCR applications than any other firm and the longest-running applications on very large utility furnaces. The total installed base includes more than 590 units firing all types of fossil, biomass, and industrial fuels. More than 50 of these applications are on coal fired units larger than 400MW, and several which are larger than 600MW. A partial experience list is provided for review in Section 12.

2. FUEL TECH SNCR PROCESS DESCRIPTION

Fuel Tech's urea-based selective non-catalytic reduction (SNCR) Process is a post-combustion NOx reduction method that reduces NOx through a controlled injection of an aqueous urea solution into the combustion gas path of fossil-fired and waste-fired boilers, furnaces, incinerators, or heaters. The most commonly used reagent consists of a 50% urea solution plus a small amount of additives for scale and corrosion control. This reagent is readily available and requires no special safety precautions for handling.

The predominant overall reaction is described as:

Fuel Tech has enhanced the basic SNCR technology by developing chemical injection hardware, widening the applicable temperature range, and process control expertise required for commercial applications. Fuel Tech's urea based SNCR technology is the NOxOUT® process. In addition to NOxOUT which utilizes low energy, air atomized injectors, Fuel Tech is also offering High Energy Reagent Technology (HERT™) which utilizes mechanically atomized injectors and carrier air for injection into the furnace.

Two key parameters that affect the process performance are flue gas temperature and the reagent distribution. The NOx reducing reaction is temperature sensitive; by-product emissions become significant at lower than the optimum temperature range while chemical utilization and NOx reduction decrease at higher than the optimum. This optimum temperature range is specific to each application. The reagent needs to be distributed within this optimum temperature zone to obtain the best performance. Typically, the distribution is more difficult for large units and for units with high flue gas velocity.

Fuel Tech's SNCR Processes are designed with the aid of Computational Fluid Dynamics (CFD) and Chemical Kinetic Model (CKM) in addition to results from field tests. The CFD model simulates flue gas flows and temperature inside a unit while the CKM calculates the reaction between urea and NOx based on temperature and flow information from CFD. A combination of these two models determines the optimum temperature region and the optimum injection strategy to distribute the reagent. With an ability to estimate NOx reduction, a model study can be performed to determine if an application is a right fit for the process.

Chemical injectors developed by Fuel Tech facilitate the reagent distribution. The NOxOUT injection system utilizes air-atomized injectors which direct the urea solution into the combustion gas path. The droplet size distribution and spray coverage developed by the injectors promote efficient contact between the chemical and the NOx in the flue gas.

The Multiple Nozzle Lance is designed to provide chemical coverage in high temperature locations where the wall injectors cannot be installed due to concerns of urea impinging on the convective surfaces. MNLs are added to the injection strategy if high levels of reduction are required, if the temperature window is very narrow due to low baseline NOx, or if the upper furnace flue gas temperature and CO concentration are excessive. Each MNL is supplied with

a retract mechanism to remove the lance from the boiler cavity when the lance is not in use, or if loss of cooling water flow, high cooling water temperature or loss of atomization air flow occurs.

Fuel Tech's SNCR Processes provide effective boiler load following capabilities. Through the computer modeling, an injection strategy is developed that makes use of multilevel injection, control of reagent concentration, droplet size and spray patterns, as well as jet penetration.

Several years of field-testing indicate that NOxOUT systems are applicable on various types of units firing many different fuels. The process was successfully proven on units fired with coal, oil, gas, wood or municipal solid or hazardous waste. These units varied in size and type: package boilers, process heaters, incinerators, circulating or bubbling fluidized beds, waste heat boilers, utility boilers. By being a post-combustion process, unit size and type and fuel type have some, but not a major effect on the process.

There are substantial benefits gained from the application of NOxOUT systems compared to first generation NOx control technologies, such as ammonia injection. These benefits are briefly summarized below:

- Use of non-toxic, non-hazardous chemicals.
- Potentially lower capital cost due to the lack of large system compressors and elimination of anhydrous ammonia storage, handling, and safety equipment.
- Lower operating costs resulting primarily from minimization of gas (steam or compressed air) requirements.
- Inherently more effective control of chemical distribution for better mixing with the use of liquid rather than gas-based reagents, thereby resulting in better chemical utilization.

Process Notes:

1. The FTEK guarantees the NOx reduction, ammonia slip, and urea flow values stated above provided that the final system is designed to the strict adherence to the model results, the baseline NOx is not higher than what is indicated on the process design table, the installation of injection ports are per FTEK's guidance, and the use of FTEK's metering and injection equipment. The performance guarantee results would be transferred to commercial performance guarantee language in the final commercial sale of equipment agreement of the SNCR System.
2. Ammonium bisulfate formation is not expected to be a concern since the S content is less than 1%.
3. For this proposal effort, the SNCR reduction system is designed to cover a load range of 185 – 600 MWg (~31 – 100% MCR). If the load range was decreased to 50 – 100% MCR, the Zone 1 Injectors (lowest level in the furnace) may be eliminated.

4. FUEL TECH SCOPE OF SUPPLY

4.1. Base Equipment Scope of Supply Summary

Equipment Summary Case 1 – Wall Injector plus MNL 10 ppm Ammonia Slip:

Equipment Description	Quantity
Reagent Storage and Circulation Module	
Aqueous Urea Truck Unloading Panel	One (1)
NOxOUT Reagent FRP Storage Tanks, Single Wall, Heat Traced and Insulated, Thirty (30) Days Storage	Four (4) 70,000 Gallon
Circulation Module, Two (2) 100% Redundant Pumps with Enclosure for outdoor placement and Return Pressure Control Station. Junction Box for Control by DCS.	One (1)
Metering, Distribution, and Injection – Indoor Placement,	
Dilution Water Module w/ Two (2) 100% Redundant Pumps. Junction Box for Control by DCS.	One (1)
Metering Module (s) w/ Junction Box for Control by DCS.	One (1) MM-HF-3Z for Wall Injectors One (1) MM-HF-1Z for MNLs
Distribution Module (s)	Eight (8) DM NX 5 Four (4) DM NX 6 One (1) DM NX 4
Injectors – NOxOUT Air Atomized Injectors	Sixty-eight (68) – NOxOUT
Automatic Retracts for Zone 1 Wall Injectors	Twenty-four (24)
Distribution Module, MNL	Two (2) – DM-MNL -2M
MNL Injectors w/Retracts, 26' Inserted Length	Four (4)
MNL cooling water Supply/Return Spool Pieces	One (1) Lot
Engineering and Field Services	
Process and Project Engineering	Included
SAMA Logic Diagrams and Functional Descriptions	Included
Field Start Up, Optimization, and Training Services	Included

Equipment Summary Case 2 – Wall Injectors Only 10 ppm Ammonia Slip:

Equipment Description	Quantity
Reagent Storage and Circulation Module	
Aqueous Urea Truck Unloading Panel	One (1)
NOxOUT Reagent FRP Storage Tanks, Single Wall, Heat Traced and Insulated, Thirty (30) Days Storage	Three (3) 70,000 Gallon
Circulation Module, Two (2) 100% Redundant Pumps with Enclosure for outdoor placement and Return Pressure Control Station. Junction Box for Control by DCS.	One (1)

Equipment Description	Quantity
Metering, Distribution, and Injection – Indoor Placement	
Dilution Water Module w/ Two (2) 100% Redundant Pumps. Junction Box for Control by DCS.	One (1)
Metering Module (s) w/ Junction Box for Control by DCS.	One (1) MM-HF-3Z for Wall Injectors
Distribution Module (s)	Eight (8) DM NX 5 Four (4) DM NX 6 One (1) DM NX 4
Injectors – NOxOUT Air Atomized Injectors	Sixty-eight (68) – NOxOUT
Automatic Retracts for Zone 1 Wall Injectors	Twenty-four (24)
Engineering and Field Services	
Process and Project Engineering	Included
SAMA Logic Diagrams and Functional Descriptions	Included
Field Start Up, Optimization, and Training Services	Included

4.2. Detailed Equipment Descriptions (REDACTED)
REDACTED

4.3. Fuel Tech Standard Manufacturer's List (REDACTED)

REDACTED

4.4. System and Equipment Engineering Services

Engineering - Fuel Tech will provide Project and Process Engineering and the following drawings:

- Process Flow Diagrams (PFDs)
- P&IDs
- Module General Arrangement Drawings
- Foundation Dead Loads
- Injector Locations
- Electrical Schematics and Bill of Materials
- Electrical Panel Layout Drawings
- Interconnection Diagrams
- SAMA Logic Diagrams and Functional Descriptions

FTEK will provide three (3) drawing submittal cycles as follows:

1. Drawings submitted for review and comment.
2. Drawings submitted for Fabrication
3. As-built Drawings as Needed

Engineering Services

- Process and Project Engineering
- Project Engineering and Project Management
- Engineering Kickoff Meeting/Bi-Weekly Update Conference Call/Webinar Meetings as Required
- Field Installation Support, Start-up, and Optimization Services
- Training Services and Training Manuals,
 - One (1) Electronic Version
 - Ten (10) hard copies
- Operation and Maintenance Manuals
 - One (1) Electronic Version
 - Four (4) Hard Copies

5. PROPOSAL DRAWINGS **(PARTIALLY REDACTED)**

The following proposal drawings are preliminary in nature and are intended to provide general reference to the equipment offering. Actual dimensions and weights will be provided during the design phase of the Project.

Figure 2 - Typical System Isometric

6. SCOPE OF SUPPLY BY OTHERS

1. Offloading of All Fuel Tech Supplied Equipment
2. Installation Labor and Materials for Fuel Tech, Inc. Supplied Equipment.
3. BOP and Installation Engineering, Installation Project Management
4. Interconnecting Piping and Wiring of Fuel Tech, Inc. Supplied Equipment.
5. No Costs were included for Performance or Bid Bonding
6. Professional Engineering Stamps if required
7. Implement Control Logic Schemes into Plant DCS (as required).
 - a. Procurement of DCS Hardware (as required)
 - b. Graphic Screens Development and Programming
 - c. SNCR-related Distributed Control System Programming
8. Air Compressors.
9. Chemical Supply: Licensed Quality or Industrial Grade urea (50% Solution).
10. Plant service water (NOxOUT® reagent) or demineralized water (unstabilized urea).
11. NOx, Ammonia, and CO Monitoring Equipment, if Required.
12. Boiler Penetrations, wall boxes, and water wall tube modifications for Injectors.
13. Boiler Scaffolding as needed
14. Tank Foundation and Structural Support for System Modules.
15. Appropriate Indoor Location/Building and Freeze Protection for FTEK Equipment as Required.
16. Permits as Required
17. Taxes as Required
18. Asbestos and Lead Paint Abatement, if Required
19. System Performance Testing
20. Spare Parts
21. Estimated System Utilities per Unit:

Description - Total	Instrument Air, SCFM (80 PSIG 70 °F)	Atomizing Air, SCFM (100 PSIG, Clean)	Dilution Water, GPM (60 PSIG/60 °F)	MNL Cooling Water, GPM (Clean, Inlet ≤ 120 °F, ≥ 150 PSIG)	Power, kW (480 or 120 VAC)
Case 1 - SNCR System w/Wall Injectors Plus MNLs	40, intermittent	1,010	145	300	95
Case 2 - SNCR System w/Wall Injectors Only	30, intermittent	720	165	N/A	75

7. UREA AND DILUTION WATER INFORMATION

7.1. Specifications for Urea and Dilution Water

Depending on the quality of water available for urea dilution at the Metering Module, either a licensed reagent (NOxOUT A or HP identified below) or unstabilized urea may be used. If an unstabilized urea of any concentration is used, the water quality requirements are much more stringent. The urea and dilution water specifications for SNCR operation with stabilized and unstabilized urea are provided below:

Quality Specifications for Aqueous Urea			
Description	NOxOUT® A	NOxOUT® HP	Unstabilized Urea
	Modified 50% Aqueous Solution of Urea	Modified 50% Aqueous Solution of Urea	50% Aqueous Solution of Urea
Density (g/ml @ 25° C)	1.13 – 1.15	1.13 – 1.15	1.085 -1.105
pH	7.0 – 10.8	7.0 -10.8	7.0 -10.8
Appearance	Light Yellow, Clear to Slightly Hazy	Light Yellow, Clear to Slightly Hazy	Light Yellow, Clear to Slightly Hazy
Salt Out Freeze Point	64 degrees F (18 degrees C)	64 degrees F (18 degrees C)	64 degrees F (18 degrees C)
Foam	Foam Lasts > 15 seconds after bottle is shaken	Foam Lasts > 15 seconds after bottle is shaken	Not Applicable
Free NH3	< 5000 ppm	< 5000 ppm	< 5000 ppm
Biuret Content	< 5000 ppm	< 5000 ppm	< 5000 ppm
Organic Phosphate	55 – 85 ppm as PO4	22 -40 ppm as PO4	Not Applicable
Orthophosphate	< 6 ppm as PO4	<6 ppm as PO4	<2 ppm as PO4
Total Suspended Solids	< 10 ppm	<10 ppm	<10 ppm
Urea Makeup Water	Total Hardness as CaCO ₃ ≤ 300 ppm	Total Hardness as CaCO ₃ ≤ 150 ppm	Total Hardness as CaCO ₃ ≤ 20 ppm

Quality Specifications for Dilution Water			
Parameter	NOxOUT® A	NOxOUT® HP	Unstabilized Urea
Total Hardness as CaCO ₃ (ppm)	<450	<150	<20

8. TYPICAL FTEK SNCR PROJECT SCHEDULE

The schedule below is typical of SNCR projects with MNLs and of similar size and scope.

EVENT	RESPONSIBILITY	WEEKS FROM ORDER DATE
Receipt of Order	Customer	0
Begin Project Design	Fuel Tech	1
Submit Preliminary P&ID and PFD Drawings	Fuel Tech	6
Customer PFD/P&ID Drawing Comments Received	Customer	8
Submit Mechanical General Arrangement Drawings	Fuel Tech	10
Customer Drawing Comments Received/Release for Procurement and Fabrication	Customer	14
Submit Electrical Drawings	Fuel Tech	14
Submit SAMAs and Functional Descriptions	Fuel Tech	20
Begin Equipment Fabrication	Fuel Tech	20
Equipment Testing and FAT	Fuel Tech/Customer	40
Equipment Shipment	Fuel Tech	44
Equipment Delivery	Fuel Tech	46
Complete Equipment Installation	Customer	TBD
Begin Start-Up & Testing	Fuel Tech	1-2 weeks after completion of installation
Begin Optimization	Fuel Tech	2-4 weeks
Compliance Testing	Customer	TBD

Notes

- Dates and durations subject to change based on contract release date and turnaround times for drawing approvals. FTEK's schedule is based on clients review and comment period of two (2) weeks or less.
- FTEK will provide three (3) drawing submittal cycles as follows:
 - Drawings submitted for review and comment.
 - Drawings submitted for Fabrication
 - As-built Drawings as Needed
- Additional drawing submittals may be provided as a cost adder.
- A more accurate schedule may be provided during a commercial proposal phase.

9. PRICING AND PAYMENT TERMS

9.1. Pricing (REDACTED)

For the design, supply, and field services for the SNCR system defined in this Proposal, FTEK quotes the preliminary and budgetary pricing of:

REDACTED

The installation shall be by others. Should additional field time be required beyond what is provided, the mandays and expenses will be invoiced per Appendix C-1, Field Service Rates. The current offering is based on FTEK standard equipment specifications and commercial terms and conditions.

9.2. Payment Terms

- 10% Upon receipt of Letter of Intent, Purchase Order, or Contract
- 40% Upon Release of fabrication by the Buyer
- 40% Upon date of shipment of equipment, or thirty days after notification to buyer that equipment is ready to ship, whichever occurs first.
- 10% After successful completion of acceptance test or six (6) months after receipt of equipment, whichever occurs first.

Subject: 50% High Purity Urea Solution

Hello Paul,

I have some budgetary numbers for you on the subject material delivered to Bismarck, ND.

We have a supply facility about an hour away that can provide the highest purity urea available which would alleviate any impurity issues within the Nox system.

50% High Purity Urea Solution FOB delivered to Bismarck, ND
\$1.35/gallon
Full Truck Load quantities are 5000 gallons

Please let me know if there's any information you require.

Best regards,

Carlos Cervantes

Attention: Paul Lee

Paul

Below is your request for budgetary pricing for Anhydrous Ammonia delivered to Bismarck, ND.

Product: Commercial Grade Anhydrous Ammonia 99.5%
Delivery: Bulk truck and driver
Quantity: 34,000 to 36,000 pounds
Product Price: \$0.2885, per pound, delivered
Freight: Included in product price
Fuel Surcharge: \$450
Hazmat Fee: Waived

Product: Premium Grade Anhydrous Ammonia 99.995%
Delivery: Bulk truck and driver
Quantity: 34,000 to 36,000 pounds
Product Price: \$0.60, per pound, delivered
Freight: Included in product price
Fuel Surcharge: \$450 estimated
Hazmat Fee: Waived

This quote is good for 60 days.

Deliveries are typically made during weekdays with four (4) hours of unloading time. Weekend and holiday deliveries are available for an additional charge. Additional unloading time will be billed at an additional \$100 per hour.

If you have any other questions please contact me.

Thank you

Lee, Paul (Denver)

Subject: RE: Corten Pricing

Hi Paul,

CW indicates a Per Hundred Pound measurement, often referred to as "Per Hundred Weight" pricing or "CWT", our system does not allow 3 letters in that field. If you changed to "\$.6950" as mentioned below, that would become the Price Per Pound. I hope this helps, the prices & totals on our quote is accurate, let me know if you have any other questions.

Jay,

Mack Van Eaton has been helping me with some estimates for steel. Your name was on the attached quote I received from them, so I figured it'd be best to ask you questions directly. The cost of coten plate is listed at 69.5 "CW", at 81,680 lbs. Multiplying the two results in 5,676,760, but your quote lists 56,767.60. Can you confirm what CW means, and that the "69.50" is actually \$0.6950?

Thank you,

Paul Lee, P.E.*

Thanks a lot Carl. I have a few outstanding questions.

I have a cost estimate for installing boiler penetrations, but it's old and likely specific to this particular client. With that said, does Babcock offer installation services, and if yes, what would it cost to install these?

Additionally, I know I didn't provide the refractory material, but since it's a general consumable during construction, would you have any idea how much a generic refractory would cost on a sq ft or tonnage basis?

Thank you,

PRIVILEGED AND CONFIDENTIAL – PREPARED AT THE DIRECTION OF COUNSEL

Carl,

Thank you for willing to help on this project. The project is looking into NOx controls, including SNCR, and for the SNCR, we would need new penetrations for the injection lances. Please see the information below, and if there's anything else you need, please let me know.

Tube Material: SA210A1

Tube OD: 1 ¾"

Membrane Thickness: ½"

Number of openings: The SNCR will need three levels of lances, one with 24 penetrations, and two levels of 20 penetrations each.

Opening Size: Each injector is 3" OD

Please let me know if you need anything else. Thank you again,

Paul Lee, P.E.*

Paul,
Thanks for the call.
We have supplied both:

- High dust SCRs on units firing lignite coal (Luminant Oak Grove Units 1&2) that had a flue gas flow of 2,485,181 acfm per SCR reactor and
- Tail-end SCRs (WE Energy Oak Creek Units 5&6 and Units 7&8) that had a peak flue gas flow of 1,613,105 acfm per SCR reactor

The scope of supply on the tail-end SCR project included that gas-to-gas heat exchanger.
We can review the current burner design to see if lower NOx emissions area feasible.
We also can provide options for gas and dual-fuel conversion including utilizing alternative fuels such as ethanol.

Sincerely,

Suzette M. Puski

Suzette,

Thanks for the assistance over the last several months on various questions, including the email chain below. We are actually still finalizing the report that your RSCR feedback supported. At the time, we focused our cost estimates on high-dust SCR's, but after some changes in direction, I'd like to approach BPEI on more "traditional tail-end SCR."

Based on the information below in my initial email, does Riley Engineering have any tail-end SCR experience in the size range requested?

I'm writing you and those copied since Riley is under BPEI, but if I should be going to someone else, please forward as necessary.

Thank you,

Subject: RE: 400075.60.1000 181010 RSCR Budgetary Quote Request

Paul,
For an RSCR application. This will not be very practical to do as the foot print gets quite large for the flue gas flow requested.
See the following plot plan for a 54 MW RSCR. That is our largest RSCR system to date. The system is modular in design so the number of compartments can be increase but we cannot go larger in compartment size due to limits of maintaining fast acting dampers. We estimate largest practical size for an RSCR is 100 MW.

For this application we recommend a traditional tail-end SCR with an induct burner and gas/gas heat exchanger. It is not as energy efficient in terms of heat recovery (75% vs 95%) as an RSCR but it is more practical in terms of footprint. It can also meet future emissions requirements if necessary. Riley has tail-end SCR experience and a lot of experience in fitting SCRs in tight spots at the economizer outlet above the air heater inlet.

If you have any questions, please give me a call. If you can provide some GAs of the plant for us to provide a better response, we'd be happy to address this further.

Sincerely,

Suzette M. Puski

Carl,

Per our phone conversation last week, please see below some information for a budgetary quote of an RSCR. I understand that the units that these are be investigated for are larger than what BPEI has done in the past, so they may not be a good fit. However, per the study that I am doing, I must at least evaluate them at a superficial level.

Parameter	Units	Case 1	Case 2
Flow rate	lb/hr	7,927,427	
	acfm	2,203,068	
Site Elevation	ft	1940	
Stack Pressure	in. w.g.	-1.1	
Fuel Burn Rate	MMBtu/hr	5,868.7	
Stack Temperature	F	147.4	
Inlet NOx	ppmvd actual O2	126	
	lb/MMBtu	0.13	
O2	Vol%,wet	4.9	
O2 reference	Vol%,dry	3.0	
H2O	Vol%,wet	16.4	
CO2	Vol%,wet	14.4	
SO2	ppmvd actual O2	48	
SO3	ppmvd actual O2	9	
Particulate	lb/hr	28.50	
Outlet NOx (guarantee)	ppmvd actual O2	39	
Ammonia Slip (guarantee)	ppmvd ref. O2	2	
SO2 to SO3 Oxidation Rate (guarantee)	%	0.5/catalyst layer	
Operating Hours (guarantee)	hours	24,000	

If you need anything else, please let me know. Thank you,

Ms. Megan Berge
Baker Botts LLP
1299 Pennsylvania Ave, NW
Washington, D.C. 20004
P: (202) 639-1308

**SUBJECT: GREAT RIVER ENERGY – REQUEST FOR PROPOSAL
COAL CREEK STATION UNIT 2 ADVANCED SCR SYSTEM
TECHNOLOGY EVALUATION AND SYSTEM COSTS
FUEL TECH BUDGETARY PROPOSAL NO. 18-B-064, ADDENDUM 1**

Dear Ms. Berge:

Fuel Tech, Inc. (FTEK) is pleased to submit our preliminary and budgetary Proposal 18-B-064, Addendum 1, to Great River Energy (GRE) for the Coal Creek Station (CCS) Unit 2. The following evaluation provides the technical, performance, and commercial details for the FTEK Advanced Selective Catalytic Reduction (ASCR™) system for CCS Unit 2 located in Underwood, ND.

FTEK's ASCR evaluation assumes the NOxOUT® Selective Non-Catalytic Reduction (SNCR) system has already been installed on CCS Unit 2 (pricing, performance, and scope provided previously under separate cover). The scope of supply for the FTEK's ASCR Process would include the ASCR system design, process review, ammonia injection grids (AIGs), and our ULTRA System Urea conversion technology to convert urea to ammonia for the AIGs. Our systems would be controlled via the Plant's Honeywell DCS System.

CC Unit 2 Unit Description and ASCR Layout:

Coal Creek Station Unit 2 is a 600 MWg Combustion Engineering tangential fired boiler with eight corners and a divided furnace. The boiler fires 100% ND lignite coal with a heat input of 5,971 MMBTU/hr at full load. The Unit has Foster Wheeler Low NOx Combustion System with close coupled over fire air (CCOFA) and separated over fire air (SOFA) systems. The NOx baseline at full load is 0.121 lb/MMBTU.

For the ASCR system layout, it is assumed the SNCR system is already deployed and is controlling NOx down to 0.103 lb/MMBTU. See FTEK's Proposal 18-B-064 for the SNCR performance. The SNCR performance utilized for the ASCR design incorporates our combined injection strategy of wall injectors + multiple nozzle lances (MNLs) with a 10 ppm ammonia slip at the economizer outlet.

The ASCR system would replace the existing ductwork from the economizer outlet to the air preheater (APH) inlet. This ASCR system would include two (2) SCR reactors that would be expanded to provide the appropriate catalyst quantity and flue gas flow distribution requirements.

Fuel Tech Inc. • 27601 Bella Vista Parkway • Warrenville, IL 60555
Phone: (970) 368-6019 • Cell: (847) 504-6650
dpfaff@ftek.com • www.ftek.com

The current SCR performance includes 2 layers of catalyst to provide 33% NO_x reduction with an ammonia slip of 2 ppm at the catalyst outlet. Each SCR reactor train would include an ammonia injection frid (AIG), turning vanes, distribution devices and catalyst reactor as highlighted in the following Figure.

Figure 1 - GRE Coal Creek Unit 2 ASCR Preliminary Layout

See Appendices for more detailed drawings of the ASCR layout.

FTEK ASCR Process Description:

NO_xOUT® Selective Non-Catalytic Reduction (SNCR) of NO_x Process

Fuel Tech's urea-based SNCR Process is a post-combustion NO_x reduction method that reduces NO_x through a controlled injection of an aqueous urea solution into the

combustion gas path of fossil-fired and waste-fired boilers, furnaces, incinerators, or heaters. The most commonly used reagent consists of a 50% urea solution plus a small amount of additives for scale and corrosion control. This reagent is readily available and requires no special safety precautions for handling.

The predominant overall reaction is described as:

Fuel Tech has enhanced the basic SNCR technology by developing chemical injection hardware, widening the applicable temperature range, and process control expertise required for commercial applications. Fuel Tech's urea based SNCR technology is the NOxOUT® process.

Two key parameters that affect the process performance are flue gas temperature and the reagent distribution. The NOx reducing reaction is temperature sensitive; by-product emissions become significant at lower than the optimum temperature range while chemical utilization and NOx reduction decrease at higher than the optimum. This optimum temperature range is specific to each application. The reagent needs to be distributed within this optimum temperature zone to obtain the best performance. Typically, the distribution is more difficult for large units and for units with high flue gas velocity.

Fuel Tech's SNCR Processes are designed with the aid of Computational Fluid Dynamics (CFD) and Chemical Kinetic Model (CKM) in addition to results from field tests. The CFD model simulates flue gas flows and temperature inside a unit while the CKM calculates the reaction between urea and NOx based on temperature and flow information from CFD. A combination of these two models determines the optimum temperature region and the optimum injection strategy to distribute the reagent. With an ability to estimate NOx reduction, a model study can be performed to determine if an application is a right fit for the process.

Chemical injectors developed by Fuel Tech facilitate the reagent distribution. The NOxOUT injection system utilizes air-atomized injectors which direct the urea solution into the combustion gas path. The droplet size distribution and spray coverage developed by the injectors promote efficient contact between the chemical and the NOx in the flue gas.

Fuel Tech's SNCR Processes provide effective boiler load following capabilities. Through the computer modeling, an injection strategy is developed that makes use of multilevel injection, control of reagent concentration, droplet size and spray patterns, as well as jet penetration.

Several years of field-testing indicate that NOxOUT systems are applicable on various types of units firing many different fuels. The process has been commercially proven on

units fired with coal, oil, gas, wood or municipal solid or hazardous waste. These units varied in size and type: package boilers, process heaters, incinerators, circulating or bubbling fluidized beds, waste heat boilers, utility boilers. By virtue of being a post-combustion process, unit size and type and fuel type have some, but not a major effect on the process.

There are substantial benefits gained from the application of NO_xOUT systems compared to first generation NO_x control technologies, such as ammonia injection. These benefits are briefly summarized below:

- Use of non-toxic, non-hazardous chemicals.
- Potentially lower capital cost due to the lack of large system compressors and elimination of anhydrous ammonia storage, handling, and safety equipment.
- Lower operating costs resulting primarily from minimization of gas (steam or compressed air) requirements.
- Inherently more effective control of chemical distribution for better mixing with the use of liquid rather than gas-based reagents, thereby resulting in better chemical utilization.

Advanced Selective Catalytic Reduction (ASCR®) of NO_x

Fuel Tech is a leader in development and deployment of a layered approach to NO_x reduction combining technologies such as combustion modifications, SNCR, and a smaller implementation of SCR catalyst. Where SCR is involved, the combination of such proven technologies has come to be known as ASCR® Advanced SCR, or ASCR.

The SCR process is a post-combustion NO_x reduction method that employs the use of catalyst to promote the conversion of nitrogen oxides (NO_x) to nitrogen and water vapor in the flue gas. This conversion occurs between the combustion area and the exhaust gas stack in a specially designed ductwork section, called the SCR Reactor, which contains the catalyst. As the NO_x and ammonia laden flue gas passes over the catalyst, the nitrogen monoxide (NO) and nitrogen dioxide (NO₂) combine with ammonia (NH₃) to form nitrogen (N₂) and water (H₂O), via the following exothermic reactions.

As long as a mixture of NO and NO₂ is present, the following faster reaction happens in parallel.

The distinguishing features that set Fuel Tech's ASCR technology apart are our commercial experience and state-of-the-art design capabilities that together allow us to

understand the working relationships of the combined NO_x reduction technologies. These capabilities also allow FTEK to evaluate each application and tailor a solution that maximizes the contribution of each technology in our suite of offerings without pushing any one process to the point that it impacts boiler operation or negatively impacts another NO_x reduction process downstream.

The ASCR process offers operational benefits due to its ability to quickly adapt to process condition changes and the fact that each deployed technology component can be optimized independently. This advantage manifests itself through a robust range of potential responses to process upsets or non-ideal operating conditions, and presents the opportunity for optimized urea consumption and lower operating costs.

Figure 2 - NO_x Reduction with Combined Technologies

By utilizing an integrated technology approach, the catalyst quantity, weight, and space requirements can be minimized, potentially leading to the elimination of new foundations and the need to install new "steel to grade". Fuel Tech works with industry leading catalyst suppliers to determine the appropriate catalyst type and formulation for each application. With the concept of a smaller implementation of catalyst compared to standalone SCR, the ASCR system has the added benefit of minimizing the rate of SO₂ to SO₃ conversion which is a precursor to ammonium sulfate/bisulfate formation in the air heater. This low conversion rate allows for a broader unit operating range and fuel

flexibility. In addition, the reduced volume of catalyst demands less time for replacement which results in shorter maintenance outages.

ASCR can be implemented in stages over time, providing financial advantages of both lower total installed capital costs and the ability to stage capital expenditures. Due to the various cost savings of a smaller SCR implementation, an ASCR system can achieve full scale SCR equivalent NOx reductions at 30-70% of the capital cost. Advanced SCR has now been applied on units up to 650 MWg.

ULTRA Process Description (Urea Conversion to Ammonia for SCR)

Fuel Tech's ULTRA™ process is a patented approach that converts safe Urea reagent to Ammonia for use on new Selective Catalytic Reduction (SCR) systems and in retrofit applications for existing systems. The ULTRA technology offers a cost effective solution for simplifying on-site ammonia generation for SCR applications of all types.

The ULTRA System provides ammonia reagent to an SCR by controlling the injection of high quality aqueous urea into a compactly and specifically designed duct maintained within the appropriate temperature window. The reactions of the ULTRA Process are described as:

The use of urea in the ULTRA System eliminates all ammonia handling requirements so that the expenses, safety, and environmental concerns are eliminated. The urea solution is readily available for delivery in solution or in dry form for on-site solutionizing and requires no special safety precautions for handling which allows the aqueous solution to be stored in atmospheric tanks.

The aqueous urea solution, at a specific flow rate, is introduced into the hot air stream in at the top of the Decomposition Chamber. The chamber is specifically designed with the appropriate flow paths, residence time and post chamber HNCO catalyst to achieve a 100% conversion of urea to ammonia product.

The urea reagent is sprayed through proprietary chemical injectors developed by Fuel Tech to facilitate the reagent distribution, droplet size, and flow rate. Utilizing pressurized air from customer's existing plant compressed air system; these injectors atomize and direct the reagent into the dilution air stream of the ULTRA System.

The airflow through the Decomposition Chamber including the urea injection will be modeled using a computational fluid dynamics model with proprietary droplet trajectory

modeling. This will insure proper evaporation, mixing, and decomposition of injected urea reagent within the heated air stream.

The gas stream leaving the Decomposition Chamber containing the SCR reagent is then routed to the AIG. The pressure, flow, and temperature are monitored to conform to the requirements of the SCR system design and to maintain proper ULTRA operations.

The control of the urea injection will be based on a hardwired reagent demand signal from the Owner's DCS. A short residence time in the decomposition chamber will allow a rapid response time for SCR reagent production. The system will be able to shutdown almost instantaneously through halting of urea injection.

The ULTRA Process thermally decomposes urea and does not involve hydrolysis. The ULTRA design and process is simple to operate and has no disposal requirements for by-products during operation, start-up, and shutdown. The added benefits include the system's ability to be brought off line quickly, with very responsive boiler load following capabilities.

The features of the ULTRA system include:

- Safe Reagent Supply
- Skid mounted system for easy installation
- No requirement for formaldehyde free urea supply
- No hazardous material disposal that is common with the hydrolysis urea conversion process.
- Simplified process and controls compared to other systems (patent pending)
- Designed for maximum system availability and minimum maintenance
- Load following controls for safe operation and easy system shutdown
- Low pressure operation
- Fuel Tech's proven experience with urea-based systems
- Experience with proven system components

System supported by Fuel Tech's field personnel with startup, optimization and service experience.

FTEK Process Performance for GRE CCS Unit 2

Unit Identification	Unit 2
Type of Unit	600 MW CE T-Fired, Eight (8) Corner, Divided Furnace
Type of Fuel	North Dakota Lignite
Load Range	100% MCR

Heat Input (Electrical Heater)	(kW)	192

For FTEK to provide system and performance guarantees, we would be responsible for the design and supply of all ASCR “smart parts” which would include the flow modeling, SCR and reagent system process design, catalyst specification and procurement, internal flow and catalyst cleaning devices, and reagent and AIG system design and procurement. For the purpose of this evaluation, our current scope only includes the ASCR process design and modeling, reagent and AIG systems design and supply, and field services. See “Scope of Supply by Others” below.

FTEK Scope of Supply

Description	Quantity
Ammonia Injection Grid, Design and Supply, Lances and Distribution Manifolds. Shipped loose for installation by Others	Two (2)
ULTRA Urea Conversion – Redundant Ambient Air Fans, Electric Heaters, Decomposition Chamber, Metering and Distribution Modules, w/Junction Boxes	Two (2)
ASCR Process Engineering Services including Flow Modeling, System Layout, Process Performance Review, and Preliminary General Arrangement Drawings for Ducts, SCR Reactor, and Internal Flow Distribution Devices	One (1) Lot

Scope of Supply by Others, BOP, and Utility Requirements

1. Offloading of All Fuel Tech Supplied Equipment
2. Installation Labor and Materials for Fuel Tech, Inc. Supplied Equipment.
3. BOP and Installation Engineering, Installation Project Management
4. Interconnecting Piping and Wiring of Fuel Tech, Inc. Supplied Equipment.
5. Demolition of Existing Ductwork
6. Building and Boiler House Structural Steel Review and Redesign to Support New ASCR Ductwork, and SCR Reactor. Review of Building Interferences.
7. Cost for Demolition, New Structural Steel, Foundations, and Boiler House Modifications as Needed.

8. Costs for New Ductwork, Internal Flue Gas Flow Distribution Devices, Catalyst, Catalyst Reactor (Ductwork, Supports, and Seals), and External Insulation.
9. Sonic Horns and SCR Cleaning Devices (quantity TBD by others)
 - a. Operated on sequencing (typically, 10 seconds every 10 minutes)
10. Evaluate ID Fan Capacity and Boiler (Implosion Study) for Additional SCR Pressure Drop. Provide Modifications/Upgrades as Needed.
11. Replacement of Stack Reheat System and All Modified Equipment.
12. No Costs were included for Performance or Bid Bonding
13. Professional Engineering Stamps if required
14. Implement Control Logic Schemes into Plant DCS (as required).
 - a. Procurement of DCS Hardware (as required)
 - b. Graphic Screens Development and Programming
 - c. SNCR-related Distributed Control System Programming
15. Project Controls – Scheduling and Master Milestone Schedule
16. Air Compressors.
17. Chemical Supply: Licensed Quality or Industrial Grade urea (50% Solution).
18. Plant service water (NOxOUT® reagent) or demineralized water (unstabilized urea).
19. NOx, Ammonia, and CO Monitoring Equipment, if Required.
20. Structural Support for System Modules.
21. Appropriate Indoor Location/Building and Freeze Protection for FTEK Equipment as Required.
22. Permits as Required
23. Taxes as Required
24. Asbestos and Lead Paint Abatement, if Required
25. System Performance Testing
26. Spare Parts
27. Estimated System Utilities, Total:

Description - Total	Instrument Air, SCFM (80 PSIG 70 °F)	Atomizing Air, SCFM (100 PSIG, Clean)	Flush Water, GPM (60 PSIG/60 °F)	Power, kW (480 VAC) ⁽¹⁾
ULTRA System, Total	10	30	2 (Intermittent)	450
	Catalyst Pressure Drop, "W.C."	SCR System Pressure Drop, "W.C."	Additional 50% Aqueous Urea Usage, GPH	Sonic Horn Air, SCFM (80 PSIG 70 °F) ⁽²⁾
ASCR, Total	2.0	4.0	36	320 (cycled, intermittent)

Note 1: Electric heaters and blowers

Note 2: Based on four (4) sonic horns being required with 40 – 80 SCFM per horn air consumption.

Schedule and Pricing:

The following is a preliminary schedule for the FTEK provided equipment and engineering:

- ASCR Modeling, Design, and Layout – Twenty (20) Weeks from Receipt of PO.
- ULTRA System and AIG Design and Supply – Thirty (30) Weeks from Receipt of PO or Twenty-Six (26) Weeks from Confirmation of ASCR Confirmed Ammonia Demand Flow.

For the components, engineering, and field technical assistance detailed in this evaluation, FTEK quotes the preliminary and budgetary pricing of ~~XXXXXXXXXXXX~~.

FTEK Recommendations and Design Concerns

FTEK has performed a "high level" evaluation of the ASCR process for GRE CCS Unit 2. As stated previously, the ASCR process is a component of a layered approach to NOx reduction combining technologies of combustion modifications/optimization, SNCR, and a smaller implementation of SCR catalyst. Upon preview of the system sizing and layout requirements, there are significant retrofit impacts for the catalyst reactors that must be considered.

The backend of Unit 2 has a split flue gas ductwork configuration leaving the economizer and entering the air heaters. Due to the ash loading of the ND Lignite at 10 – 12% ash and an "Si + Al" total > 80%, the ash particles are harder and may be erosive at higher velocities. Therefore, the catalyst face velocity has to be lowered to ~ 15 fps to minimize catalyst erosion. The ductwork expansion required to achieve adequate face velocities while providing adequate NOx reduction will require significant retrofit design consideration and will prove very costly. The ASCR duct expansion would require changes to and redesign of both the existing boiler structural steel and the stack reheat system.

In addition to the spatial limitations, FTEK has several process concerns regarding the sodium (Na) levels in the fuel/ash and sulfur trioxide (SO3) levels in flue gas. SO3 in the presence of ammonia (NH3) in the form of ammonia slip from the SCR process could lead to ammonium bisulfate plugging in the air heater. Additionally, the SO3 concentration in the flue gas may convert the Na in the solid phase to a gaseous phase which may cause significant catalyst deactivation.

To provide acceptable NOx reduction "activity" and catalyst life expectancy, the existing catalyst formulation has a ~2% oxidation rate per layer. This will cause SO2 in the flue gas to be converted to SO3 which in turn could lead to ammonium bisulfate pluggage of the catalyst and air heater along with accelerated catalyst deactivation rates due to Na poisoning.

Great River Energy
Coal Creek Station Unit 2
ASCR Budgetary Evaluation

December 20, 2018
Proposal 18-B-064, Addm 1
Page 13

For these reasons, FTEK would not recommend the deployment of the ASCR technology on CCS Unit 2. We would not be willing to provide any performance guarantees on the SCR portion at this time until more is known about the effects of ND lignite ash on catalyst performance and deactivation. FTEK would recommend that pilot scale testing should be performed to obtain actual operational data and learn more about the ND Lignite and prove catalyst operation and performance.

We trust this information meets your needs. Upon completion of your review, please do not hesitate to contact me if there are any questions or comments. Thank you.

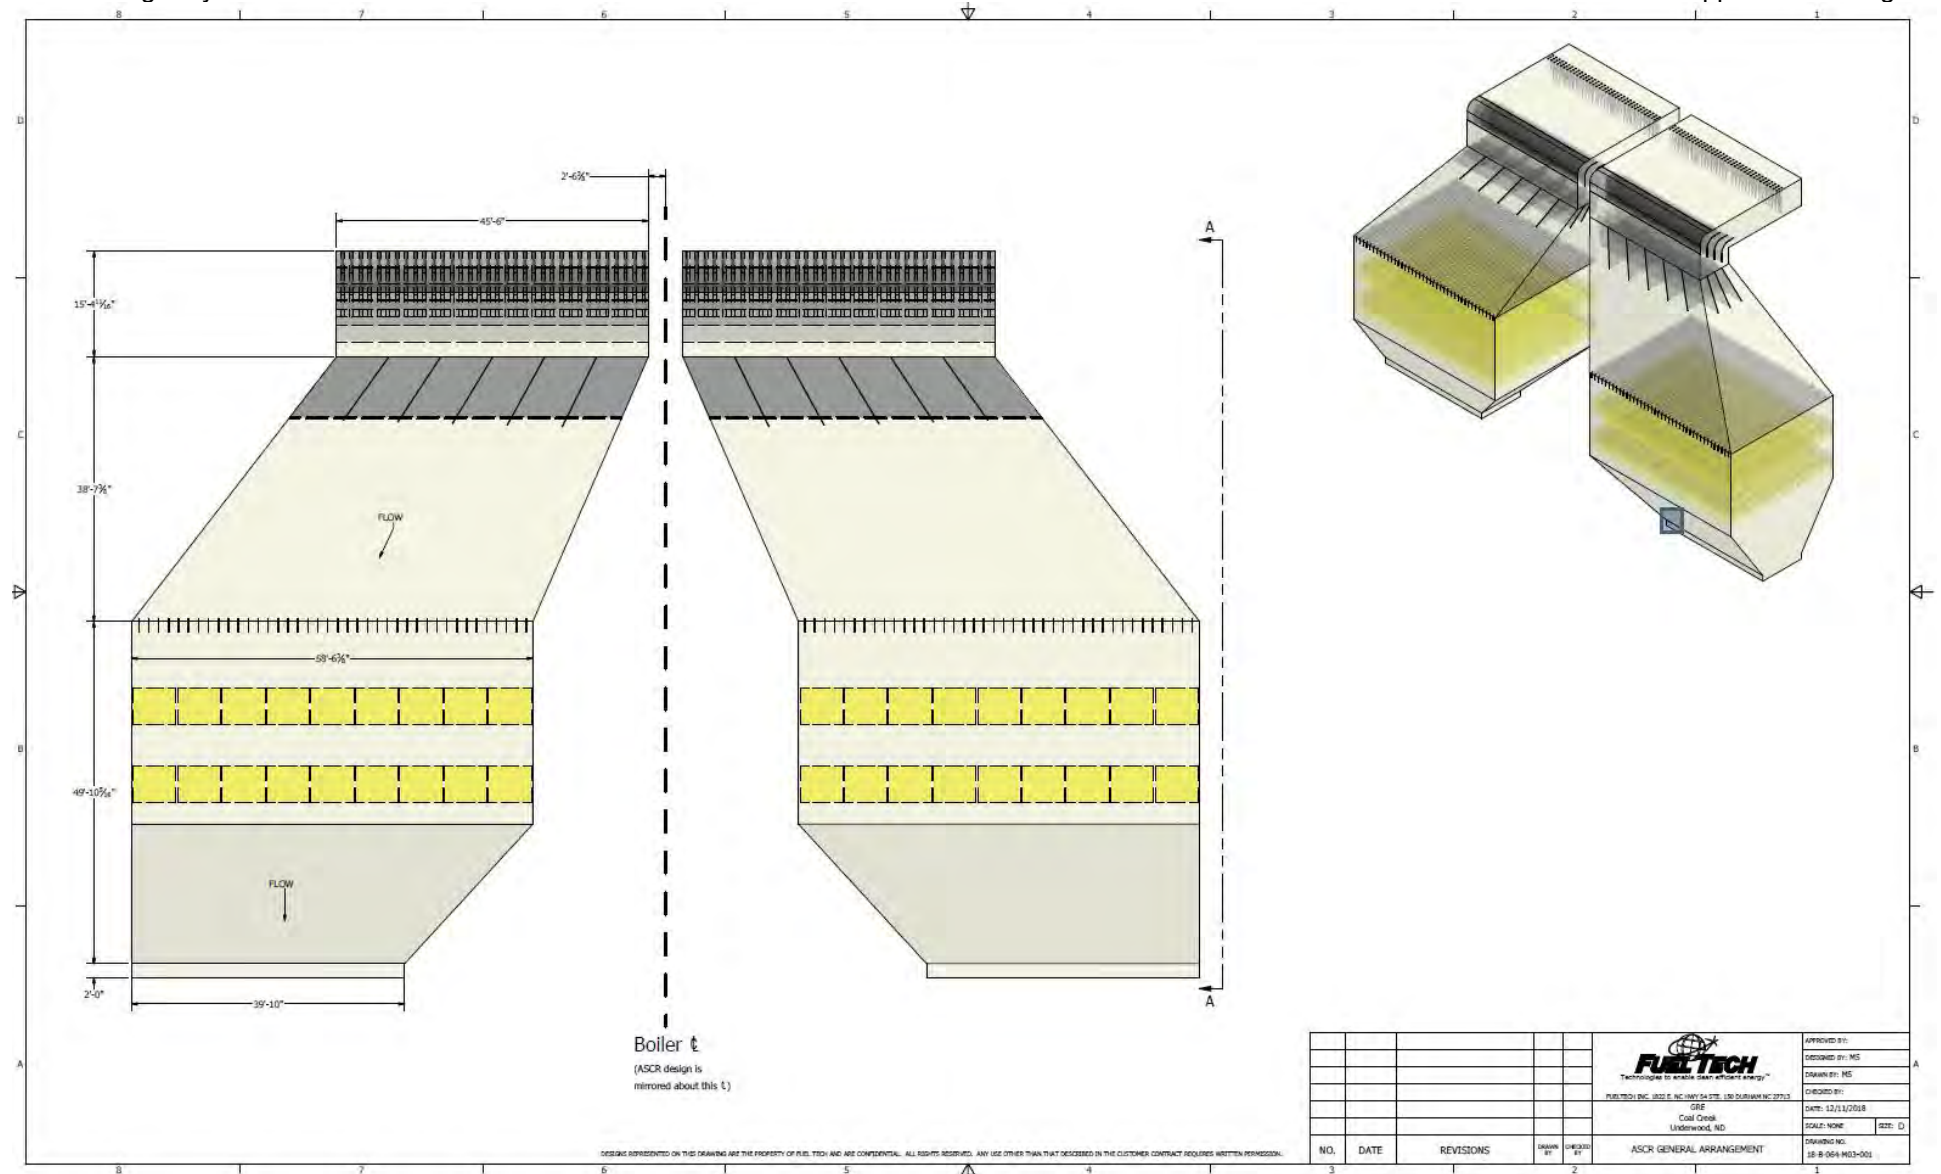

Sincerely,

Dale Pfaff
Regional Sales Manager

Appendix G. EPA Cost Manual Cost Estimate Sheets

Data Inputs

Enter the following data for your combustion unit:

Is the combustion unit a utility or industrial boiler?

Utility ▼

What type of fuel does the unit burn?

Coal ▼

Is the SCR for a new boiler or retrofit of an existing boiler?

Retrofit ▼

Please enter a retrofit factor between 0.8 and 1.5 based on the level of difficulty. Enter 1 for projects of average retrofit difficulty.

1

Complete all of the highlighted data fields:

What is the MW rating at full load capacity (Bmw)?

563.42 MW

What is the higher heating value (HHV) of the fuel?

6,612 Btu/lb

What is the estimated actual annual MWhs output?

4,293,936 MWhs

Enter the net plant heat input rate (NPHR)

10.416 MMBtu/MW

If the NPHR is not known, use the default NPHR value:

Fuel Type	Default NPHR
Coal	10 MMBtu/MW
Fuel Oil	11 MMBtu/MW
Natural Gas	8.2 MMBtu/MW

Plant Elevation

1980 Feet above sea level

Provide the following information for coal-fired boilers:

Type of coal burned:

Lignite ▼

Enter the sulfur content (%S) =

0.61 percent by weight

For units burning coal blends:

Note: The table below is pre-populated with default values for HHV and %S. Please enter the actual values for these parameters in the table below. If the actual value for any parameter is not known, you may use the default values provided.

Coal Type	Fraction in Coal Blend	%S	HHV (Btu/lb)
Bituminous	0	1.84	11,841
Sub-Bituminous	0	0.41	8,826
Lignite	0	0.82	6,685

Please click the calculate button to calculate weighted average values based on the data in the table above.

For coal-fired boilers, you may use either Method 1 or Method 2 to calculate the catalyst replacement cost. The equations for both methods are shown on rows 85 and 86 on the **Cost Estimate** tab. Please select your preferred method:

- ☐ Method 1
☒ Method 2
☐ Not applicable

Enter the following design parameters for the proposed SCR:

Number of days the SCR operates (t_{SCR})

318 days

Number of days the boiler operates (t_{plant})

318 days

Inlet NO_x Emissions (NO_{x,in}) to SCR

0.13 lb/MMBtu

Outlet NO_x Emissions (NO_{x,out}) from SCR

0.04 lb/MMBtu

Stoichiometric Ratio Factor (SRF)

1.050

*The SRF value of 1.05 is a default value. User should enter actual value, if known.

Estimated operating life of the catalyst ($H_{catalyst}$)

24,000 hours

Estimated SCR equipment life

30 Years*

* For utility boilers, the typical equipment life of an SCR is at least 30 years.

Concentration of reagent as stored (C_{stored})

100 percent

Density of reagent as stored (ρ_{stored})

38.55 lb/cubic feet

Number of days reagent is stored ($t_{storage}$)

30 days

Select the reagent used

Ammonia

Number of SCR reactor chambers (n_{scr})

1

Number of catalyst layers (R_{layer})

3

Number of empty catalyst layers (R_{empty})

1

Ammonia Slip (Slip) provided by vendor

2 ppm

Volume of the catalyst layers ($Vol_{catalyst}$)
(Enter "UNK" if value is not known)

UNK Cubic feet

Flue gas flow rate ($Q_{fluegas}$)

(Enter "UNK" if value is not known)

3,202,636 acfm

Gas temperature at the SCR inlet (T)

830 °F

Base case fuel gas volumetric flow rate factor (Q_{fuel})547 ft³/min-MMBtu/hour

Densities of typical SCR reagents:

50% urea solution

71 lbs/ft³29.4% aqueous NH₃56 lbs/ft³

Enter the cost data for the proposed SCR:

Desired dollar-year

2018

CEPCI for 2018

615.3 Enter the CEPCI value for 2018

541.7

2016 CEPCI

CEPCI = Chemical Engineering Plant Cost Index

Annual Interest Rate (i)

5.25 Percent

Reagent (Cost_{reag})

1.560 \$/gallon for 100% ammonia

Electricity (Cost_{elect})

0.0329 \$/kWh

Catalyst cost (CC_{replace})\$ /cubic foot (includes removal and disposal/regeneration of existing
118.20 catalyst and installation of new catalyst

Operator Labor Rate

71.81 \$/hour (including benefits)

Operator Hours/Day

4.00 hours/day*

* 4 hours/day is a default value for the operator labor. User should enter actual value, if known.

Note: The use of CEPCI in this spreadsheet is not an endorsement of the index, but is there merely to allow for availability of a well-known cost index to spreadsheet users. Use of other well-known cost indexes (e.g., M&S) is acceptable.

Maintenance and Administrative Charges Cost Factors:

Maintenance Cost Factor (MCF) =	0.005
Administrative Charges Factor (ACF) =	0.03

SCR Design Parameters

The following design parameters for the SCR were calculated based on the values entered on the *Data Inputs* tab. These values were used to prepare the costs shown on the *Cost Estimate* tab.

Parameter	Equation	Calculated Value	Units
Maximum Annual Heat Input Rate (Q_B) =	$Bmw \times NPHR =$	5,869	MMBtu/hour
Maximum Annual MW Output (Bmw) =	$Bmw \times 8760 =$	4,935,559	MWhts
Estimated Actual Annual MWhts Output (Boutput) =		4,293,936	MWhts
Heat Rate Factor (HRF) =	$NPHR/10 =$	1.04	
Total System Capacity Factor (CF_{total}) =	$(Boutput/Bmw) \times (t_{scr}/t_{plant}) =$	0.870	fraction
Total operating time for the SCR (t_{op}) =	$CF_{total} \times 8760 =$	7621	hours
NO _x Removal Efficiency (EF) =	$(NO_{x_{in}} - NO_{x_{out}})/NO_{x_{in}} =$	69.2	percent
NO _x removed per hour =	$NO_{x_{in}} \times EF \times Q_B =$	528.17	lb/hour
Total NO _x removed per year =	$(NO_{x_{in}} \times EF \times Q_B \times t_{op})/2000 =$	2,012.65	tons/year
NO _x removal factor (NRF) =	$EF/80 =$	0.87	
Volumetric flue gas flow rate ($q_{flue\ gas}$) =	$Q_{fuel} \times Q_B \times (460 + T)/(460 + 700)n_{scr} =$	3,202,636	acfm
Space velocity (V_{space}) =	$q_{flue\ gas}/Vol_{catalyst} =$	135.19	/hour
Residence Time	$1/V_{space}$	0.01	hour
Coal Factor (CoalF) =	1 for oil and natural gas; 1 for bituminous; 1.05 for sub-bituminous; 1.07 for lignite (weighted average is used for coal blends)	1.07	
SO ₂ Emission rate =	$(\%S/100) \times (64/32) \times 1 \times 10^6 / HHV =$	< 3	lbs/MMBtu
Elevation Factor (ELEVf) =	$14.7\ psia/P =$	1.07	
Atmospheric pressure at sea level (P) =	$2116 \times [(59 - (0.00356 \times h) + 459.7)/518.6]^{5.256} \times (1/144)^* =$	13.7	psia
Retrofit Factor (RF)	Retrofit to existing boiler	1.00	

* Equation is from the National Aeronautics and Space Administration (NASA), Earth Atmosphere Model. Available at <https://spaceflightsystems.grc.nasa.gov/education/rocket/atmos.html>.

Catalyst Data:

Parameter	Equation	Calculated Value	Units
Future worth factor (FWF) =	$(interest\ rate)(1/((1 + interest\ rate)^Y - 1))$, where $Y = H_{catalysts}/(t_{SCR} \times 24\ hours)$ rounded to the nearest integer	0.3164	Fraction
Catalyst volume ($Vol_{catalyst}$) =	$2.81 \times Q_B \times EF_{adj} \times Slip_{adj} \times NO_{x_{adj}} \times S_{adj} \times (T_{adj}/N_{scr})$	23,689.22	Cubic feet
Cross sectional area of the catalyst ($A_{catalyst}$) =	$q_{flue\ gas} / (16\ ft/sec \times 60\ sec/min)$	3,336	ft ²

Height of each catalyst layer (H_{layer}) =	$(Vol_{catalyst} / (R_{layer} \times A_{catalyst})) + 1$ (rounded to next highest integer)	3	feet
---	--	---	------

SCR Reactor Data:

Parameter	Equation	Calculated Value	Units
Cross sectional area of the reactor (A_{SCR}) =	$1.15 \times A_{catalyst}$	3,836	ft ²
Reactor length and width dimensions for a square reactor =	$(A_{SCR})^{0.5}$	61.9	feet
Reactor height =	$(R_{layer} + R_{empty}) \times (7ft + h_{layer}) + 9ft$	50	feet

Reagent Data:

Type of reagent used

Ammonia

Molecular Weight of Reagent (MW) = 17.03 g/mole

Density = 38.55 lb/ft³

Parameter	Equation	Calculated Value	Units
Reagent consumption rate (m_{reagent}) =	$(\text{NOx}_{\text{in}} \times Q_{\text{B}} \times \text{EF} \times \text{SRF} \times \text{MW}_{\text{R}}) / \text{MW}_{\text{NOx}} =$	205	lb/hour
Reagent Usage Rate (m_{sol}) =	$m_{\text{reagent}} / \text{Csol} =$	205	lb/hour
	$(m_{\text{sol}} \times 7.4805) / \text{Reagent Density}$	40	gal/hour
Estimated tank volume for reagent storage =	$(m_{\text{sol}} \times 7.4805 \times t_{\text{storage}} \times 24) / \text{Reagent Density} =$	28,700	gallons (storage needed to store a 30 day reagent supply rounded to

Capital Recovery Factor:

Parameter	Equation	Calculated Value
Capital Recovery Factor (CRF) =	$i (1+i)^n / (1+i)^n - 1 =$ Where n = Equipment Life and i= Interest Rate	0.0669

Other parameters	Equation	Calculated Value	Units
Electricity Usage:			
Electricity Consumption (P) =	$A \times 1,000 \times 0.0056 \times (\text{CoalF} \times \text{HRF})^{0.43} =$ where A = Bmw for utility boilers	3305.73	kW

Cost Estimate

Total Capital Investment (TCI)

TCI for Coal-Fired Boilers

For Coal-Fired Boilers:

$$TCI = 1.3 \times (SCR_{cost} + RPC + APHC + BPC)$$

Capital costs for the SCR (SCR_{cost}) =	\$137,775,430	in 2018 dollars
Reagent Preparation Cost (RPC) =	\$3,071,151	in 2018 dollars
Air Pre-Heater Costs (APHC)* =	\$0	in 2018 dollars
Balance of Plant Costs (BPC) =	\$9,657,516	in 2018 dollars
Total Capital Investment (TCI) =	\$195,655,325	in 2018 dollars

* Not applicable - This factor applies only to coal-fired boilers that burn bituminous coal and emits equal to or greater than 3lb/MMBtu of sulfur dioxide.

SCR Capital Costs (SCR_{cost})

For Coal-Fired Utility Boilers >25 MW:

$$SCR_{cost} = 310,000 \times (NRF)^{0.2} \times (B_{MW} \times HRF \times CoalF)^{0.92} \times ELEVF \times RF$$

For Coal-Fired Industrial Boilers >250 MMBtu/hour:

$$SCR_{cost} = 310,000 \times (NRF)^{0.2} \times (0.1 \times Q_B \times CoalF)^{0.92} \times ELEVF \times RF$$

SCR Capital Costs (SCR_{cost}) =

\$137,775,430 in 2018 dollars

Reagent Preparation Costs (RPC)

For Coal-Fired Utility Boilers >25 MW:

$$RPC = 564,000 \times (NO_{x,in} \times B_{MW} \times NPHR \times EF)^{0.25} \times RF$$

For Coal-Fired Industrial Boilers >250 MMBtu/hour:

$$RPC = 564,000 \times (NO_{x,in} \times Q_B \times EF)^{0.25} \times RF$$

Reagent Preparation Costs (RPC) =

\$3,071,151 in 2018 dollars

Air Pre-Heater Costs (APHC)*

For Coal-Fired Utility Boilers >25MW:

$$APHC = 69,000 \times (B_{MW} \times HRF \times CoalF)^{0.78} \times AHF \times RF$$

For Coal-Fired Industrial Boilers >250 MMBtu/hour:

$$APHC = 69,000 \times (0.1 \times Q_B \times CoalF)^{0.78} \times AHF \times RF$$

Air Pre-Heater Costs (APH_{cost}) =

\$0 in 2018 dollars

* Not applicable - This factor applies only to coal-fired boilers that burn bituminous coal and emit equal to or greater than 3lb/MMBtu of sulfur dioxide.

Balance of Plant Costs (BPC)

For Coal-Fired Utility Boilers >25MW:

$$BPC = 529,000 \times (B_{MW} \times HRF \times CoalF)^{0.42} \times ELEVF \times RF$$

For Coal-Fired Industrial Boilers >250 MMBtu/hour:

$$BPC = 529,000 \times (0.1 \times Q_B \times CoalF)^{0.42} \times ELEVF \times RF$$

Balance of Plant Costs (BOP_{cost}) =

\$9,657,516 in 2018 dollars

Annual Costs

Total Annual Cost (TAC)

$$\text{TAC} = \text{Direct Annual Costs} + \text{Indirect Annual Costs}$$

Direct Annual Costs (DAC) =	\$3,313,274 in 2018 dollars
Indirect Annual Costs (IDAC) =	\$13,103,821 in 2018 dollars
Total annual costs (TAC) = DAC + IDAC	\$16,417,095 in 2018 dollars

Direct Annual Costs (DAC)

$$\text{DAC} = (\text{Annual Maintenance Cost}) + (\text{Annual Reagent Cost}) + (\text{Annual Electricity Cost}) + (\text{Annual Catalyst Cost})$$

Annual Maintenance Cost =	$0.005 \times \text{TCl} =$	\$978,277 in 2018 dollars
Annual Reagent Cost =	$m_{\text{sol}} \times \text{Cost}_{\text{reag}} \times t_{\text{op}} =$	\$473,567 in 2018 dollars
Annual Electricity Cost =	$P \times \text{Cost}_{\text{elect}} \times t_{\text{op}} =$	\$828,869 in 2018 dollars
Annual Catalyst Replacement Cost =		\$1,032,561 in 2018 dollars

For coal-fired boilers, the following methods may be used to calculate the catalyst replacement cost.

Method 1 (for all fuel types): $n_{\text{scr}} \times \text{Vol}_{\text{cat}} \times (\text{CC}_{\text{replace}} / R_{\text{layer}}) \times \text{FWF}$ * Calculation Method 2 selected.

Method 2 (for coal-fired utility boilers): $B_{\text{MW}} \times 0.4 \times (\text{CoalF})^{2.9} \times (\text{NRF})^{0.71} \times (\text{CC}_{\text{replace}}) \times 35.3$

Direct Annual Cost =	\$3,313,274 in 2018 dollars
----------------------	-----------------------------

Indirect Annual Cost (IDAC)

$$\text{IDAC} = \text{Administrative Charges} + \text{Capital Recovery Costs}$$

Administrative Charges (AC) =	$0.03 \times (\text{Operator Cost} + 0.4 \times \text{Annual Maintenance Cost}) =$	\$14,480 in 2018 dollars
Capital Recovery Costs (CR)=	$\text{CRF} \times \text{TCl} =$	\$13,089,341 in 2018 dollars
Indirect Annual Cost (IDAC) =	$\text{AC} + \text{CR} =$	\$13,103,821 in 2018 dollars

Cost Effectiveness

$$\text{Cost Effectiveness} = \text{Total Annual Cost} / \text{NOx Removed/year}$$

Total Annual Cost (TAC) =	\$16,417,095 per year in 2018 dollars
NOx Removed =	2,013 tons/year
Cost Effectiveness =	\$8,157 per ton of NOx removed in 2018 dollars

Data Inputs

Enter the following data for your combustion unit:

Is the combustion unit a utility or industrial boiler?

Utility ▼

What type of fuel does the unit burn?

Coal ▼

Is the SNCR for a new boiler or retrofit of an existing boiler?

Retrofit ▼

Please enter a retrofit factor equal to or greater than 0.84 based on the level of difficulty. Enter 1 for projects of average retrofit difficulty.

1

Complete all of the highlighted data fields:

What is the MW rating at full load capacity (Bmw)?

563.42 MW

What is the higher heating value (HHV) of the fuel?

6,612 Btu/lb

What is the estimated actual annual MWh output?

4,293,936 MWh

Is the boiler a fluid-bed boiler?

No ▼

Enter the net plant heat input rate (NPHR)

10.416 MMBtu/MW

If the NPHR is not known, use the default NPHR value:

Fuel Type	Default NPHR
Coal	10 MMBtu/MW
Fuel Oil	11 MMBtu/MW
Natural Gas	8.2 MMBtu/MW

Provide the following information for coal-fired boilers:

Type of coal burned:

Lignite ▼

Enter the sulfur content (%S) =

0.61 percent by weight

or

Select the appropriate SO₂ emission rate:

Not Applicable ▼

Ash content (%Ash):

12.89 percent by weight

For units burning coal blends:

Note: The table below is pre-populated with default values for HHV, %S, %Ash and cost. Please enter the actual values for these parameters in the table below. If the actual value for any parameter is not known, you may use the default values provided.

	Fraction in Coal Blend	%S	%Ash	HHV (Btu/lb)	Fuel Cost (\$/MMBtu)
Bituminous	0	1.84	9.23	11,841	2.4
Sub-Bituminous	0	0.41	5.84	8,826	1.89
Lignite	0	0.82	13.6	6,626	1.74

Please click the calculate button to calculate weighted values based on the data in the table above.

Enter the following design parameters for the proposed SNCR:

Number of days the SNCR operates (t_{SNCR})

365 days

Plant Elevation

1980 Feet above sea level

Inlet NO_x Emissions ($\text{NO}_{x,\text{in}}$) to SNCR

0.13 lb/MMBtu

Outlet NO_x Emissions ($\text{NO}_{x,\text{out}}$) from SNCR

0.1105 lb/MMBtu

Estimated Normalized Stoichiometric Ratio (NSR)

3.33

*The NSR for a urea system may be calculated using equation 1.17 in Section 4, Chapter 1 of the Air Pollution Control Cost Manual (as updated March 2019).

Concentration of reagent as stored (C_{stored})

SNCR Design Parameters

The following design parameters for the SNCR were calculated based on the values entered on the *Data Inputs* tab. These values were used to prepare the costs shown on the *Cost Estimate* tab.

Parameter	Equation	Calculated Value	Units
Maximum Annual Heat Input Rate (Q_B) =	$B_{mw} \times NPHR =$	5,869	MMBtu/hour
Maximum Annual MWh Output =	$B_{mw} \times 8760 =$	4,935,559	MWh
Estimated Actual Annual MWh Output (Boutput) =		4,293,936	MWh
Heat Rate Factor (HRF) =	$NPHR/10 =$	1.04	
Total System Capacity Factor (CF_{total}) =	$(Boutput/B_{mw}) \times (tsnrcr/365) =$	0.87	fraction
Total operating time for the SNCR (t_{op}) =	$CF_{total} \times 8760 =$	7621	hours
NOx Removal Efficiency (EF) =	$(NO_{x_{in}} - NO_{x_{out}})/NO_{x_{in}} =$	15	percent
NOx removed per hour =	$NO_{x_{in}} \times EF \times Q_B =$	114.44	lb/hour
Total NO _x removed per year =	$(NO_{x_{in}} \times EF \times Q_B \times t_{op})/2000 =$	436.08	tons/year
Coal Factor ($Coal_F$) =	1 for bituminous; 1.05 for sub-bituminous; 1.07 for lignite (weighted average is used for coal blends)	1.07	
SO ₂ Emission rate =	$(\%S/100) \times (64/32) \times (1 \times 10^6)/HHV =$	< 3	lbs/MMBtu
Elevation Factor (ELEV _F) =	$14.7 \text{ psia}/P =$	1.07	
Atmospheric pressure at 1980 feet above sea level (P) =	$2116 \times [(59 - (0.00356 \times h) + 459.7)/518.6]^{5.256} \times (1/144)^* =$	13.7	psia
Retrofit Factor (RF) =	Retrofit to existing boiler	1.00	

* Equation is from the National Aeronautics and Space Administration (NASA), Earth Atmosphere Model. Available at <https://spaceflightsystems.grc.nasa.gov/education/rocket/atmos.html>.

Reagent Data:

Type of reagent used

Urea

 Molecular Weight of Reagent (MW) = 60.06 g/mole
 Density = 71 lb/gallon

Parameter	Equation	Calculated Value	Units
Reagent consumption rate (m_{reagent}) =	$(\text{NOx}_{\text{in}} \times Q_{\text{B}} \times \text{NSR} \times \text{MW}_{\text{R}}) / (\text{MW}_{\text{NOx}} \times \text{SR}) =$ (where SR = 1 for NH_3 ; 2 for Urea)	1658	lb/hour
Reagent Usage Rate (m_{sol}) =	$m_{\text{reagent}} / C_{\text{sol}} =$	3,316	lb/hour
	$(m_{\text{sol}} \times 7.4805) / \text{Reagent Density} =$	349.4	gal/hour
Estimated tank volume for reagent storage =	$(m_{\text{sol}} \times 7.4805 \times t_{\text{storage}} \times 24 \text{ hours/day}) / \text{Reagent Density} =$	251,600	gallons (storage needed to store a 30 day reagent supply rounded up to the nearest 100 gallons)

Capital Recovery Factor:

Parameter	Equation	Calculated Value
Capital Recovery Factor (CRF) =	$i (1+i)^n / (1+i)^n - 1 =$ Where n = Equipment Life and i= Interest Rate	0.0820

Parameter	Equation	Calculated Value	Units
Electricity Usage: Electricity Consumption (P) =	$(0.47 \times \text{NOx}_{\text{in}} \times \text{NSR} \times Q_{\text{B}}) / \text{NPHR} =$	114.6	kW/hour
Water Usage: Water consumption (q_{w}) =	$(m_{\text{sol}} / \text{Density of water}) \times ((C_{\text{stored}} / C_{\text{inj}}) - 1) =$	0	gallons/hour
Fuel Data: Additional Fuel required to evaporate water in injected reagent (ΔFuel) =	$H_v \times m_{\text{reagent}} \times ((1/C_{\text{inj}}) - 1) =$	1.49	MMBtu/hour
Ash Disposal: Additional ash produced due to increased fuel consumption (Δash) =	$(\Delta\text{fuel} \times \% \text{Ash} \times 1 \times 10^6) / \text{HHV} =$	29.1	lb/hour

Cost Estimate

Total Capital Investment (TCI)

For Coal-Fired Boilers:

$$TCI = 1.3 \times (SNCR_{cost} + APH_{cost} + BOP_{cost})$$

For Fuel Oil and Natural Gas-Fired Boilers:

$$TCI = 1.3 \times (SNCR_{cost} + BOP_{cost})$$

Capital costs for the SNCR ($SNCR_{cost}$) =	\$4,177,101 in 2018 dollars
Air Pre-Heater Costs (APH_{cost})* =	\$0 in 2018 dollars
Balance of Plant Costs (BOP_{cost}) =	\$5,191,356 in 2018 dollars
Total Capital Investment (TCI) =	\$12,178,995 in 2018 dollars

* Not applicable - This factor applies only to coal-fired boilers that burn bituminous coal and emits equal to or greater than 0.3lb/MMBtu of sulfur dioxide.

SNCR Capital Costs ($SNCR_{cost}$)

For Coal-Fired Utility Boilers:

$$SNCR_{cost} = 220,000 \times (B_{MW} \times HRF)^{0.42} \times CoalF \times BTF \times ELEVF \times RF$$

For Fuel Oil and Natural Gas-Fired Utility Boilers:

$$SNCR_{cost} = 147,000 \times (B_{MW} \times HRF)^{0.42} \times ELEVF \times RF$$

For Coal-Fired Industrial Boilers:

$$SNCR_{cost} = 220,000 \times (0.1 \times Q_B \times HRF)^{0.42} \times CoalF \times BTF \times ELEVF \times RF$$

For Fuel Oil and Natural Gas-Fired Industrial Boilers:

$$SNCR_{cost} = 147,000 \times ((Q_B/NPHR) \times HRF)^{0.42} \times ELEVF \times RF$$

SNCR Capital Costs ($SNCR_{cost}$) =	\$4,177,101 in 2018 dollars
--	-----------------------------

Air Pre-Heater Costs (APH_{cost})*

For Coal-Fired Utility Boilers:

$$APH_{cost} = 69,000 \times (B_{MW} \times HRF \times CoalF)^{0.78} \times AHF \times RF$$

For Coal-Fired Industrial Boilers:

$$APH_{cost} = 69,000 \times (0.1 \times Q_B \times HRF \times CoalF)^{0.78} \times AHF \times RF$$

Air Pre-Heater Costs (APH_{cost}) =	\$0 in 2018 dollars
---	---------------------

* Not applicable - This factor applies only to coal-fired boilers that burn bituminous coal and emit equal to or greater than 3lb/MMBtu of sulfur dioxide.

Balance of Plant Costs (BOP_{cost})

For Coal-Fired Utility Boilers:

$$BOP_{cost} = 320,000 \times (B_{MW})^{0.33} \times (NO_x \text{ Removed/hr})^{0.12} \times BTF \times RF$$

For Fuel Oil and Natural Gas-Fired Utility Boilers:

$$BOP_{cost} = 213,000 \times (B_{MW})^{0.33} \times (NO_x \text{ Removed/hr})^{0.12} \times RF$$

For Coal-Fired Industrial Boilers:

$$BOP_{cost} = 320,000 \times (0.1 \times Q_B)^{0.33} \times (NO_x \text{ Removed/hr})^{0.12} \times BTF \times RF$$

For Fuel Oil and Natural Gas-Fired Industrial Boilers:

$$BOP_{cost} = 213,000 \times (Q_B/NPHR)^{0.33} \times (NO_x \text{ Removed/hr})^{0.12} \times RF$$

Balance of Plant Costs (BOP_{cost}) =	\$5,191,356 in 2018 dollars
---	-----------------------------

Annual Costs

Total Annual Cost (TAC)

$$\text{TAC} = \text{Direct Annual Costs} + \text{Indirect Annual Costs}$$

Direct Annual Costs (DAC) =	\$3,828,504 in 2018 dollars
Indirect Annual Costs (IDAC) =	\$1,004,158 in 2018 dollars
Total annual costs (TAC) = DAC + IDAC	\$4,832,662 in 2018 dollars

Direct Annual Costs (DAC)

$$\text{DAC} = (\text{Annual Maintenance Cost}) + (\text{Annual Reagent Cost}) + (\text{Annual Electricity Cost}) + (\text{Annual Water Cost}) + (\text{Annual Fuel Cost}) + (\text{Annual Ash Cost})$$

Annual Maintenance Cost =	$0.015 \times \text{TCI} =$	\$182,685 in 2018 dollars
Annual Reagent Cost =	$q_{\text{sol}} \times \text{Cost}_{\text{reag}} \times t_{\text{op}} =$	\$3,594,871 in 2018 dollars
Annual Electricity Cost =	$P \times \text{Cost}_{\text{elect}} \times t_{\text{op}} =$	\$28,743 in 2018 dollars
Annual Water Cost =	$q_{\text{water}} \times \text{Cost}_{\text{water}} \times t_{\text{op}} =$	\$0 in 2018 dollars
Additional Fuel Cost =	$\Delta \text{Fuel} \times \text{Cost}_{\text{fuel}} \times t_{\text{op}} =$	\$21,041 in 2018 dollars
Additional Ash Cost =	$\Delta \text{Ash} \times \text{Cost}_{\text{ash}} \times t_{\text{op}} \times (1/2000) =$	\$1,164 in 2018 dollars
Direct Annual Cost =		\$3,828,504 in 2018 dollars

Indirect Annual Cost (IDAC)

$$\text{IDAC} = \text{Administrative Charges} + \text{Capital Recovery Costs}$$

Administrative Charges (AC) =	$0.03 \times \text{Annual Maintenance Cost} =$	\$5,481 in 2018 dollars
Capital Recovery Costs (CR)=	$\text{CRF} \times \text{TCI} =$	\$998,678 in 2018 dollars
Indirect Annual Cost (IDAC) =	$\text{AC} + \text{CR} =$	\$1,004,158 in 2018 dollars

Cost Effectiveness

$$\text{Cost Effectiveness} = \text{Total Annual Cost} / \text{NOx Removed/year}$$

Total Annual Cost (TAC) =	\$4,832,662 per year in 2018 dollars
NOx Removed =	436 tons/year
Cost Effectiveness =	\$11,082 per ton of NOx removed in 2018 dollars

Data Inputs

Enter the following data for your combustion unit:

Is the combustion unit a utility or industrial boiler?

Utility ▼

What type of fuel does the unit burn?

Coal ▼

Is the SNCR for a new boiler or retrofit of an existing boiler?

Retrofit ▼

Please enter a retrofit factor equal to or greater than 0.84 based on the level of difficulty. Enter 1 for projects of average retrofit difficulty.

1

Complete all of the highlighted data fields:

What is the MW rating at full load capacity (Bmw)?

563.42 MW

What is the higher heating value (HHV) of the fuel?

6,612 Btu/lb

What is the estimated actual annual MWh output?

4,293,936 MWh

Is the boiler a fluid-bed boiler?

No ▼

Enter the net plant heat input rate (NPHR)

10.416 MMBtu/MW

If the NPHR is not known, use the default NPHR value:

Fuel Type	Default NPHR
Coal	10 MMBtu/MW
Fuel Oil	11 MMBtu/MW
Natural Gas	8.2 MMBtu/MW

Provide the following information for coal-fired boilers:

Type of coal burned:

Lignite ▼

Enter the sulfur content (%S) =

0.61 percent by weight

or

Select the appropriate SO₂ emission rate:

Not Applicable ▼

Ash content (%Ash):

12.89 percent by weight

For units burning coal blends:

Note: The table below is pre-populated with default values for HHV, %S, %Ash and cost. Please enter the actual values for these parameters in the table below. If the actual value for any parameter is not known, you may use the default values provided.

	Fraction in Coal Blend	%S	%Ash	HHV (Btu/lb)	Fuel Cost (\$/MMBtu)
Bituminous	0	1.84	9.23	11,841	2.4
Sub-Bituminous	0	0.41	5.84	8,826	1.89
Lignite	0	0.82	13.6	6,626	1.74

Please click the calculate button to calculate weighted values based on the data in the table above.

Enter the following design parameters for the proposed SNCR:

Number of days the SNCR operates (t_{SNCR})

Cost Effectiveness =	\$7,279 per ton of NOx removed in 2018 dollars

Appendix H. Alstom Power MATS Tuning Report

Great River Energy

Coal Creek Station

Unit's #1 and #2

MATS Tuning

EXECUTIVE SUMMARY REPORT

June 2015

EXECUTIVE SUMMARY

Alstom Power Technical Services was on site beginning the week of 6/8/2015 to conduct a series of emissions tests under the MATS ruling. The testing/tuning consisted of monitoring flue gas emission for O₂, NO_x and CO while the units were operated at full load conditions. Data was collected before, during and after all matrix parameter adjustments.

Coal Creek Units #1 and #2 are Alstom Power designed CCRRD steam generators (Controlled Circulation Radiant Reheat Divided Furnace). The MCR (Maximum Continuous Rating) of each unit is 3,730 Klbs/hr. steam flow. The unit's burn North Dakota lignite through eight (8) elevations of pulverized coal, supplied by Alstom designed 1043 RP mills. Design operating pressure is 2,620 psi.

Alstom Power Testing Services had installed a twelve (12) point sampling test grid across the furnace backpass, just after the economizer outlet for each unit tested. Vacuum pumps pulled a continuous flue gas sample through our analyzer system and this gas sample was monitored for O₂, (% dry) CO (ppm) and NO_x (#/MMBtu).

Alstom followed a test matrix to affect either a positive or negative response to manipulated parameters. This test matrix included the following parameters that were adjusted with controller biases:

- WB/F ΔP
- O₂
- Burner tilts
- SOFA tilts
- SOFA dampers

UNIT #2

The following data was monitored and recorded at the beginning of each parameter adjustment. The first set of data is recorded as “base load” at the start of tuning on 6/10/2015. Unit #2 was tested first.

Plant Data

- Load 606 MW
- Throttle Press. 2520 psi
- SHO (L/R) 994/989° F
- RHO (L/R) 987/997° F
- Mills in Service 6
- Tilts (L/R) 9/19 degrees up
- O₂ Plant 2.75 %
- WB/F ΔP 5.3”
- NO_x .152 #/MMBtu (plant CEMS)

Alstom Test Grid

- O₂ 3.2 %
- CO 8.5 ppm
- NO_x .148 #/MMBtu

Alstom began making adjustments to the WB/F ΔP controller bias. The as found output of 5.3” was incrementally increased up to 6.2” by removing the negative bias of .9” that had been installed earlier by GRE. These small step adjustments brought the NO_x down to:

- CEMS .139 #/MMBtu
- Alstom .141 #/MMBtu

The following spreadsheet shows flue gas analysis of all 12 Alstom grid intersects on our point-to-point sampling. The sheet indicates the grid depth and length across the economizer outlet ducts, both Left and Right.

The above data shows sampling points across the economizer outlet duct on June 10th, after the unit reached a steady state of full load and prior to making a parameter adjustment. Note the low CO values and NO_x ppm and #/MMBtu output.

From 6/10 through 6/12, Alstom manipulated O₂, WB/F ΔP, Burner tilts, SOFA tilts and SOFA dampers. The O₂ adjustments were small (2.75% to 2.5% range) and did not affect the NO_x output positively. WB/F ΔP adjustments accounted for the best positive effect in further reducing the already good NO_x output. No amount of adjustments to the units SOFA yaw or dampers mechanisms made any positive NO_x reduction. In fact, the SOFA system is so well tuned, that any all adjustments from in-place control, only made the NO_x value increase.

GREAT RIVER ENERGY
COAL CREEK #2
SOFA YAW POSTIONS

This diagram shows the optimum positioning of SOFA yaws on Unit #2, in a range of +15 to -15 degrees. These positions should not be modified. In addition, the SOFA damper control curves for the Upper and Lower SOFA compartments are working quite well and should not be modified.

The above graph shows NOx output reduction on Unit #2 after making adjustments to increase WB/F ΔP .

NOx output after final parameter adjustments made to Unit #2. Ending average was .138 to .140 #/MMBtu.

Plant Data

- Load 612MW
- O2 2.6%
- WB/FΔP 6.2"
- SHO 992/985 degrees
- RHO 1005/1004 degrees
- CEMS .140 #/MMBtu

Alstom Grid .139 #/MMBtu NOx 5.1 ppm CO

UNIT #1

Unit #1 was tested the week of 6/15, using the same equipment installed in the unit's economizer backpass and following the same matrix. Although this was only one week after testing was conducted on Unit #2, there were significant changes noted in operation of both units. While Unit #2 had recorded a relatively low NOx output (.139 #/MMBtu), Unit #1 was operating with a low NOx output as well. While in the Control Room, Alstom noted that Unit #1 NOx was at .181 to .183 #/MMBtu. This value is well below the permitted value of .226 #/MMBtu. However, during our week of testing on Unit #2, the NOx level had increased up to .218, with occasional spikes up to .226 #/MMBtu. We also noted that the NOx output on Unit #2 had increased as well, up to an average of .165, from our low tested point of .139 #/MMBtu average.

After discussions with GRE, we were informed that the fuel quality had changed, to the detriment of NOx increases on both units. The fuel quality change was enough that neither unit was able to achieve and maintain design SH and RH outlet temperatures. As a result, operators had raised the burner tilts to compensate for the loss of steam temperatures. Operating with burner tilts greater than 0° (horizontal) will over-stage the Low NOx system (staging is the term associated with the total distance between the Top of the burner OFA compartments and the Bottom of the SOFA compartments).

Further discussions with GRE personnel revealed the fuel quality change was not related to a reduction of HHV (Btu content) so much, but rather a change in Sodium content. GRE stated that when burning North Dakota lignite with a Sodium content of 2.0% or less, slagging conditions within the furnace cavity is virtually non-existent. With no slag/ash build up on the units Water Walls, the heat absorption rate in the lower furnace (from Nose Arch to Lower Couton Slope) is at its maximum. This rate of heat absorption in the Water Wall circuits takes away heat that would typically be absorbed in the upper SH/RH and Back Pass areas.

As a result of this fuel change, both unit burner tilts were raised in an attempt to increase SH and RH steam outlet temperatures. Tilt positions on both units averaged from +14 / +22 degrees (Left and Right furnaces). As stated prior, raising burner tilts above the horizontal plane has a negative effect on NOx emissions.

Screen shot taken from Alstom grid On Unit #1 emissions on 6/15/2015. Note the NOx at .213 #/MMBtu. While still below its permitted level, this value is higher than the previous week with operating conditions being identical. The increased NOx output is directly related to burner tilts being elevated to obtain design SH and RH outlet steam temperatures.

The following spreadsheet shows flue gas analysis of all 12 Alstom grid intersects on our point-to-point sampling. The sheet indicates the grid depth and length across the economizer outlet ducts, both Left and Right.

6/15/2015 Board Data (Unit #1)

- Load 606 MW
- Throttle Press 2522 psig
- SHO 1004/995 F
- RHO 1005/1002
- Mills in Service 6
- Burner Tilts 11/22 degrees up
- O₂ plant 2.6 % set point
- WB/F ΔP 5.2"
- NO_x .216 #/MMBtu (CEMS)

Alstom Test Grid

- O₂ 3.3 % (dry)
- CO 4 ppm
- NO_x .217 #/MMBtu

Alstom began testing / tuning with several changes made to WB/F dP increases to impart a greater spin to the fireball. In addition, changes were made to the CCOFA air compartments, located just above the upper elevation burner compartment (Mill #8). See graph shown on next page.

Graph showing results of parameters changes on NOx at beginning of tuning on 6/15/2015. Major change was from manual tilt decrease.

GREAT RIVER ENERGY COAL CREEK #1 SOFA YAW POSTIONS

This diagram shows the optimum positioning of SOFA yaws on Unit #1, in a range of +15 to -15 degrees. As with Unit #2, these positions should not be modified. In addition, the SOFA damper control curves for the Upper and Lower SOFA compartments are working quite well and should not be modified.

The above graph indicates NOx emission on the Alstom grid after all changes / adjustments made to parameters. The low average of .198 #/MMBtu was the best NOx obtainable with the low Sodium fuel for that week. NOx at beginning of tuning was averaging .221 #/MMBtu

Parameters adjusted in matrix

- O₂
- WB/F ΔP
- Burner tilts
- SOFA dampers
- SOFA Tilts

CONCLUSIONS / RECOMMENDATIONS

GRE Coal Creek Units #1 and #2 NOx emissions were found to be below current State and Federal standards prior to Alstom making additional parameter adjustments. GRE has spent considerable effort to accomplish this goal in-house. These units are well maintained and operated. Based on our discovery during the tuning process, each unit required only minimal adjustments to certain parameters to improve overall NOx and CO emission reduction. The units SOFA system is so well tuned for full load operation that any deviance from the current in-place control curve will actually increase, rather than decrease, the NOx and CO output. Based on our testing and unit evaluation of operating controls, Coal Creek Units #1 and #2 have been optimized to its full potential for NOx and CO reduction.

To maintain the low NOx and CO output levels that GRE Coal Creek units #1 and #2 are capable of, Alstom's offers these recommendations:

- The current WB/F ΔP curves work well as it is. Do not apply a negative bias to the controllers. Alstom removed the $-.9''$ bias at the start of the tuning on Unit #1 and changed a bias to Unit #1 ($+1.1''$). NOx was notably reduced.
- Alstom found a positive bias on 9 out of the 12 operating mill air flows (total for both units), ranging from 10 to 13%. It is believed that these biases were made during periods of pulverizing wet coal and were then not taken out when fuel conditions changed to dry. Excessive Primary Air through the mills typically increases the pulverized fuel ignition points and results in increased NOx and CO. If possible, limit the amount of air flow positive bias to 5 to 7%.

- During periods of low load operation, utilize the retract blowers to clean both the SH and RH pendant assemblies, including the back pass areas. The cleaner these surfaces remain, the lower the burner tilts may be operated from, which will further reduce NOx output.
- Coal fineness sampling was conducted on all mills and results showed that the % fineness through the 200 mesh screen was below design on all mills, with some as low as 54%. Design rating is 70% through the 200 mesh. GRE should continue to run performance evaluation on the mills, making adjustments where required, to obtain the design value.
- After concluding the MATS testing/tuning on Coal Creek Units 1 and 2, Alstom returned to the site to observe operating conditions on both boilers the week of 6/24. GRE informed Alstom that a higher level Sodium lignite had been delivered, with a Na content of 3.7% or higher. The operating results (NOx emissions) with this higher Sodium content fuel was significant. With all control parameter the same as the previous week, and at full load, the following data was observed on the plants CEMS.

Unit #1 NOx

.170 #/MMBtu

Unit #2 NOx

.122 #/MMBtu

The higher Na content produced additional slag/ash build up on both units Water Wall surfaces, which resulted in somewhat less heat absorption in the lower furnace. This in turn brought higher flue gas temperatures into the SH and RH Pendant sections, which allowed for the burner tilts to be lowered from +14/+22 degrees (avg.) to +3/+8 average. This reduced staging distance was responsible for the significantly lower NOx emission. Alstom recommends burning a fuel with a Sodium content average greater than 3%, if possible.

MATS Testing/Tuning
Daily Report
Wednesday, 6-10-2015

Unit Status – 10:50 am

Load – 606 mw Gross Throttle Pressure – 2510
Tilts – 15/24 degrees (L-R) CEMS NOx - .153 #/MMBtu
SHO – 994/989 RHO – 987/997
6 mills in service (2-3-4-5-6-7). Mills 1 and 8 out.
WB/F dP – 5.3" – but has -.9" bias.
Air Flow – 97.8%
Fuel Flow – 82.5%
Stm Flow – 4024 Klbs/hr.
Alstom Test Grid NOx - .147 #/MMBtu / 109 ppm.
 CO – 8 ppm

12:55
Began removing bias from WB/F dP. -.9" to -.6".

NOx trending down. CEMS - .140 Grid - .141

13:30
Changed WB/F dP bias from -.6" to -.3"

CEMS - .138 Grid - .142

14:05
Removed all bias from WB/F dP

CEMS - .135 Grid - .141. CO still low at 4 to 6 ppm.

15:10

CEMS - .135 #/MMBtu

Grid - .141 #/MMBtu

16:30 Status

Load – 611 – NOTE: Increased steam temps gave us an additional 7MW.

SHO – 996/978 RHO – 1006/1004 NOx .138 NOx -= .143

Overall NOx did decrease, primarily due to removal of all bias on WB/F dP controller.

GRE Coal Creek Unit #2
MATS Testing/Tuning
Daily Report
Thursday, 6-11-2015

Load remained steady at +600 MW through the night.

7:30 Status

Load – 610 MW CEMS NO_x - .149 #/MMBtu Grid - .155
Tilts – 15/25 WB/F dP – 6.2” (no bias) O₂ sp at 2.6%

NOTE:

NO_x higher this morning even though WB/F dP has no bias. GRE says we may have had a coal quality change. However, total TPH federate appears to be the same as 6/10. Tilts are raised more than yesterday as well and in auto, even though SH and RH temps are higher. Operator to blow some selected IK's to raise SH and RH outlet even more. This should result in tilts lowering.

NOTE:

After blowing 4 retracts in the Reheat area, NO_x decreased some, from .149 to .145 on CEMS and .155 to .149 on Alstom grid. Will continue to blow a few more IK's.

Plan for today to remove mill air flow biases. According to GRE, these biases were placed on the mill air flow controllers when they received wet coal. Once drier fuel was provided, operators never took the biases back out. This mill air flow reduction (however slight) should decrease NO_x somewhat.

09:00

Removed air flow bias from #7 mill 10% to 0.

9:35

Lowered RIGHT tilts (East) in manual from 24 to 20 degrees to lower NOx. By 9:50, had them down to 15 degrees. NOx slowly trending down.

10:00

Removed bias from #6 mill (13 to 0)

10:20

Removed bias from #5 mill (15 to 0)

11:00

Removed bias from #4 mill (10 to 0)

NOTE: #3 mill had no bias in controller.

11:20

Removed bias from #2 mill (20 to 0)

13:30

Placed LEFT tilts in manual and lowered from 11 to 8 degrees to see if NOx would decrease further.

Daily Report
Friday 6-12-2015

7:30 Status

Unit ran at full or near full load all night. No problems reported.

Load – 612 MW CEMS NO_x - .144 #/MMBtu

O₂ - 2.6% set point WB/F dP – 6.2”

SHO – 992/985 RHO – 1005/1004

Tilts – 9/18 degrees

8:20

Began testing by manually closing down on Lower SFA dampers from 50% to 45% open. NO_x increased from .145 to .151

8:45

Closed back Lower SOFA dampers from 45% to 40% open. NO_x increased again from .151 to .154

9:00

Placed lower SOFA dampers back in auto. Within 15 minutes NO_x decreased back to .147/

9:05

Decreased O₂ set point from 2.6 to 2.5%. NO_x to .144.

9:20

Lowered SOFA tilts (manually) from +22 degree average to 10 degrees up. NO_x immediately began to increase. By the time we had them all (8), NO_x had increased up to .170 on CEMS and .169 on Alstom grid.

Brought all SOFA tilts to “as found” positions and NO_x decreased back down to .139 to .140 #/MMBtu. No more testing conducted for day.

Began taking down test equipment from Unit #2 and moving it to Unit #1.
Will pull probes and re-install on Monday.

Graph showing NOx fluctuations with small load drop in morning and then NOx increase with SOFA tilt manipulation (+22 degrees to +10 degrees up).

GRE Coal Creek Unit #1
MATS Testing/Tuning
Daily Report
Monday 6-15-2015

8:00 Status

Load – 605 MW CEMS NOx .216 #/MMBtu
6 mills in service 2-3-4-5-6-7 Mills 1 and 8 off
O2 set point is 2.6%
WB/F dP - 5.2" with a +.9" bias
SHO 1004/995 RHO – 1005/1002
Tilts – 11/22 degrees.

NOTE:

NOx is higher today than last week at same load. GRE states this is due to change in coal quality. Will first work on increasing WB/F dP. Unit #1 has a plus bias installed. Unit #2 had a Minus bias installed. Difference is due to size of SOFA compartments on #2 being larger and more efficient for NOx reduction.

11:15

Increased WB/F dP bias from +.9 to +1.1"
WB/F dP now 5.4". Slight improvement in NOx to .210

13:00

WB/F dP bias increase to +1.3". Now reading 5.5" Do not want to go any further for now.

NOTE:

Mills are swinging from 84% feeder speed up to 90%. This is continuous and has been since 8:00 am. This is a significant amount of coal input change with 6 mills in service.

14:20

Lowered Lower CCOFA dampers from 50% to 45% open for NOx change

14:25

Changed Lower CCOFA dampers from 45 to 40% open . Have not seen any decrease in NOx.

14:35

Opened Lower CCOFA to 60%

15:15

Opened Lower CCOFA to 70% open. No real improvement in NOx reduction.

GRE Coal Creek Unit #1

Daily Report
Tuesday 6-16-2015

7:00

Unit still down from last night load drop. 340 MW's. Dispatch bringing load up slow.

9:50

Load now at 603 MW NOx - .229
WB/F dP – 5.2" Night shift removed 1.3" bias.
Tilts – 14/22 degrees. This is high and due to low RHO temps.
SHO – 998/1005 RHO – 1007/996

NOTE

Fuel quality down today, per GRE. 882 TPH total at 603 MW

10:15

Lowering Right side (A) tilts in manual from 22 then 18 then 15 degrees to effect NOx change.

10:30

NOx decreased from .228 to .214 #/MMBtu. Lowered Left side (B) tilts in manual from 14 to 10 degrees to effect NOx reduction.

10:40

Placed the 1.3" plus bias back into WB/F dP controller.

10:50

Now have both tilts in manual and at 11/12 degrees

SHO – 990/990

RHO – 996/977

NOx - .200 #/MMBtu

Will continue to allow SH and RH temps to drop to effect NOx reduction.

10:55

SHO – 980/986

RHO – 992/969

NOx - .194 #/MMBtu

11:00

SHO – 983/989

RHO – 991/969

NOx - .195 #/MMBtu

11:15

SHO – 984/989

RHO – 989/970

NOx - .195 #/MMBtu

11:20

Lowered O2 set point from 2.6 down to 2.5%

11:40

SHO – 980/985

RHO – 993/968

NOx - .188 #/MMBtu

11:50

SHO – 987/992

RHO – 994/973

NOx - .196 #/MMBtu

12:50

Raised Right side tilts back to 14 degrees up for additional temp

SHO – 992/995

RHO – 991/977

NOx - .199 #/MMBtu

12:55

Raising tilts back up to place in auto.

13:15

As a test, placing #8 mill in service. Hope to gain additional SH/RH temp so that tilts will come down. Even though adding an upper mill can hurt NOx, having the tilts lower is more than enough of an offset to help with total NOx.

15:50

#8 mill back off. SH and RH temps did not increase and Tilts remain high. End result was increased NOx...from .221 to .236 #/MMBtu.

7:30 Status

Load – 603 MW CEMS NOx - .216

Tilts – 10/21 degrees

SHO – 989-987

RHO – 992-988

NOTE

Operator had Right side (East) tilts in manual and at a lower position that auto would have driven them. Requested tilts be placed back in auto to bring SH and RH temps back up. Will attempt WB/F dP change (less) today to see if temps may go up.

09:00

Tilts – 10/21

SHO – 1001-1003

RHO – 1008-1004

NOx - .215 #/MMBtu

NOTE.

RH – SH temps up after blowing selected IK's

09:10

Increased WB/F dP from 1.3" up to 1.8" + bias.

11:30

Tilts – 12/20

SHO – 1003-996

RHO – 1002-1003

NOx - .218

12:05

Lowered Right tilts to 18 degrees in manual.

12:35

Tilts – 12/18

SHO – 1001-997

RHO – 1004-1000

NOx - .214

13:45

Tilts – 13/16

SHO – 989-1001

RHO – 1005-987

NOx - .215

13:50

Changing WB/F dP from +1.8" to .9" bias for a test to see if temps increase.

14:00

Tilts – 15/16

SHO – 993-1003

RHO – 1005-985

NOx. - .236

14:05

NOx increased with lowered WB/F dP change. Increased bias back to 1.8"

14:25

Increased WB/F dP bias again to +2.0". WB/F dP now 6.2"

14:45

Tilts – 15/16

SHO – 992/1002

RHO – 1006/983

NOx - .225

15:35

Tilts – 12/16

SHO – 989/982

RHO – 981/969

NOx - .208 #/MMBtu

16:10

Tilts back in auto and raising back up to regain lost SH/RH temps.

GRE Coal Creek Unit #1
MATS Testing/Tuning
Daily Report
Thursday 6-18-2015

7:45 Status

Load – 596 MW CEMS NOx .203 #/MMBtu
Tilts – 13-22
SHO – 978-967
RHO – 968-961 WB/F dP – 6.1”

NOTE: Placed 2.0” bias back into WB/F dP controller.

NOTE:

Fuel quality down again today on both units. Neither can make or maintain SH and RH Outlet temps, even with tilts raised up. NOx values on both 1&2 are not too bad, but no temperatures. Waterwalls on both units are very clean. They appear to be exhibiting full heat absorption in the WW circuits, where is decreasing flue gas temps in the upper furnace and backpass areas, resulting in loss of SHO and RHO steam temperatures. Each unit is also losing about 8 MW's due to low steam temps.

09:00

Comparison of operating conditions with clean furnaces:

UNIT #1

Tilts – 12/22
SHO – 989-979
RHO – 971-972
NOx - .210
Load – 598 mw

UNIT #2

Tilts – 20/23
SHO – 952-954
RHO – 961-942
NOx - .154
Load – 598 – mw

NOx Limit .226

NOx Limit .165

Comparison indicates NOx output to be below limits on both units. However, both units cannot make or maintain SHO and RHO steam temperatures, even with tilts raised. Both units' waterwalls are very clean.

GRE has advised that fuel quality is good, but sodium content is low. This conditions results in less sticky ash and leaves the waterwall surfaces clean, allowing for better heat absorption.

11:15

Comparison

Unit #1

Unit #2

Tilts – 10-18

Tilts – 20-23

SHO – 974-963

SHO – 949-937

RHO – 956-956

RHO – 947-932

NOx - .196

NOx - .146

12:00

Complete tuning attempts on Unit #1.

COST ESTIMATE DETAILS

1.0 INTRODUCTION

Great River Energy (GRE) has requested that Golder Associates, Inc. (Golder) prepare a third-party cost evaluation to address the potential impact the installation of selective non-catalytic reduction (SNCR) control technology would have on the existing GRE fly ash disposal and sales at Coal Creek Station (CCS) located in Underwood, North Dakota. Evaluations were prepared in relation to the United States Environmental Protection Agency's (EPA's) approval of the North Dakota State Implementation Plan (SIP). Based on the proposed SIP, GRE is evaluating SNCR control technology to reduce nitrogen oxide (NO_x) emissions from CCS. If SNCR is installed at CCS, there is potential for unreacted ammonia in the flue gas downstream of the SNCR, called ammonia slip, as well as higher ammonia concentration in fly ash. Higher ammonia concentrations in fly ash are likely to affect beneficial use, sales, and disposal of fly ash at CCS. Due to the significant impact of ammonia concentrations in fly ash on current beneficial use and sales, GRE is evaluating a potential ammonia slip mitigation (ASM) technology patented by Boral Resources (Boral) that would allow for treatment of fly ash for beneficial use and sales.

Golder performed a third-party review and estimated costs associated with implementation of Boral's ASM technology as applied to CCS. The review includes an estimate of the capital and operating and maintenance (O&M) costs for implementation of the ASM technology at CCS, with a focus on potential impacts to ash marketing and future sales to assist GRE in determining the feasibility of the ASM technology for operations at CCS. This evaluation is limited in scope given that Boral has not conducted any field scale assessment on application of this technology to lignite-derived fly ash, nor has Boral implemented this technology commercially at a size comparable to CCS (total tons of fly ash and tons per day of fly ash). The limited experience in commercial application and lack of field trials is not adequate for Boral to be able to provide any guarantee that the process can be successfully applied to treat lignite ash at the Coal Creek.

Based on the potential impacts of ammonia concentrations to fly ash sales, and the evaluation of the ASM technology, Golder prepared a cost comparison for three fly ash management scenarios at CCS:

- Scenario A: CCS's current fly ash sale rate (approximately 80% of fly ash produced is sold);
- Scenario B: No fly ash sales;
- Scenario C: Application of ASM technology (approximately 60% of fly ash produced is sold).

The cost evaluation includes a comparison of capital and O&M costs for each scenario assuming a new facility for each scenario meets EPA Coal Combustion Residual (CCR) regulations (EPA 2015).

1.1 Qualifications

Golder Associates Corporation is a global, employee-owned organization providing consulting, design, and construction services in our specialist areas of earth, environment, and energy through technical excellence, innovative solutions, and award-winning client service. Since our founding in 1960, our more than 6,500 people operating from 165 offices worldwide deliver deep technical understanding, cross-disciplinary thinking, and a passion to help our clients succeed. The United States operating company, Golder Associates, Inc., employs approximately 1,200 people in 50 offices and 5 laboratories.

This project was conducted by a team based in our Lakewood, Colorado office. The project team was well-suited to perform the proposed services for CCS because of the experience of our technical staff on comparable projects and our familiarity with the geotechnical and engineering properties of EPA CCR Rule landfill designs.

Additionally, our team has a firm understanding of the engineering practice and regulatory environment surrounding coal-fired power plants, both in North Dakota and nationwide.

2.0 SNCR IMPACT TO FLY ASH MARKETABILITY

The potential impact to fly ash marketability is a function of the SNCR ammonia slip adsorption onto the fly ash particles and the acceptable (allowable) ammonia levels in fly ash by end users.

2.1 Ammonia Adsorption onto Fly Ash

Based on available literature, the adsorption of ammonia onto fly ash from SNCR emission controls is highly variable and dependent upon factors such as SNCR operation, fuel type/fuel mix, boiler configuration, ash content, ash mineralogy, ash alkalinity, ash sulfur content, and temperature. Limited published data are available for ammonia levels in fly ash for coal-fired power plants utilizing SNCR emissions controls, with no published information being found for energy generation facilities burning lignite coal.

In a 2007 EPRI study on the handling, disposal, and sale of ammoniated fly ash (EPRI 2007), responses from eight units utilizing SNCRs were discussed. All the units fired a PRB/eastern bituminous coal blend, were predominantly smaller units, were predominantly wall-fired, and had actual ammonia slip up to 5 parts per million (ppm). Only four units had tested levels of ammonia in the fly ash, with the measured levels ranging from less than 100 ppm to over 200 ppm. Several references attempt to relate the amount of ammonia slip to the ammonia levels in fly ash and suggest that a 2-ppm ammonia slip may result in fly ash ammonia levels from less than 50 ppm to several hundred ppm (Murarka 2003, Bittner 2001, Hinton 2012, Larrimore 2002). In addition, when explaining ash sales impacts at CCS, Sahu (2011) references a figure created by Larrimore (2002) that indicates ammonia slip levels above 2 ppm can lead to “restricted use” of fly ash and ammonia slip levels above 4 ppm may lead to “unmarketable” fly ash for use in ready mix.

GRE recently contracted with a Fuel Tech, Inc. (Fuel Tech) to evaluate the potential for implementing SNCR technology at CCS and potential ammonia slip adsorption onto the fly ash (Fuel Tech 2019). As a part of that study, Fuel Tech indicated that ammonia slip is difficult to predict but was assumed to be between 5 ppm and 10 ppm, as this range is typical for units burning coal with sulfur content below 1%. In addition, Fuel Tech stated that “...an ammonia slip of 2 ppm is not really viable, as this concentration is within instrument error” due to non-linear instrument calibration issues. Fuel Tech indicated that under steady state operation if the ammonia slip is 5 ppm, the ammonia adsorbed onto fly ash should not be expected to exceed 50 ppm. Similarly, if the ammonia slip is 10 ppm, the ammonia adsorbed onto fly ash should not be expected to exceed 100 ppm.

2.2 Allowable Ammonia Present in Fly Ash

The amount of “allowable” ammonia present in fly ash destined for beneficial use varies depending on ash marketer preferences and the ultimate end use. Higher concentrations of ammonia present in fly ash are a result of ammonia slip in SCR or SNCR systems (EPRI 2007). Fly ash impacted with elevated levels of ammonia results in ammonia being released into the air when water is added. At low levels, ammonia is a nuisance; however, at higher exposure levels, ammonia can cause irritation of the eyes, throat, and nose as well as difficulty breathing (NIOSH 2011). Strength characteristics do not appear to be affected by the presence of ammonia in fly ash (Rathbone and Robl 2001).

Elevated concentrations of ammonia in fly ash contribute to releases into the environment during placement (with the presence of water), and a reluctance of fly ash marketers and users (i.e. Boral, Lafarge, etc.) to buy fly ash for sales to the construction industry. EPRI (2007) explains that the “...industry rule-of-thumb indicates that ammonia

contamination on fly ash that is destined for concrete/cement utilization must have less than 100 ppm ammonia to be useable.” Headwaters Energy Services indicated (January 11, 2010) that they “...quit shipping anything over 100 ppm...” in reference to the Eastlake facility, which had an SNCR system since 2007. Eastlake has attempted to decrease ammonia content in the fly ash to less than 50 ppm using ASM to improve fly ash marketability. Lafarge (January 26, 2010) has found “...when the ammonia levels exceed 40 part per million in the fly ash that the consumer notices the ammonia and finds it to be objectionable.” Additional references have generally found that 100 ppm is the approximate maximum “acceptable” ammonia level in fly ash (Bittner et al. 2001, Giampa 2000, Bittner and Gasiorowski 2005). Other sources cite 100 ppm as an acceptable allowable ammonia level in fly ash for enclosed spaces but allow a higher limit of 200 ppm in well ventilated areas (Brendel et al. 2000, Larrimore 2002).

The amount of ammonia in fly ash can be related to the ammonia off-gassed during placement. Both NIOSH and OSHA have health-based exposure limits for ammonia in the air. NIOSH has a recommended exposure limit (REL) of 25 ppm and OSHA’s permissible exposure limit (PEL) is 50 ppm. A “comfortable” threshold of 10 ppm ammonia is referenced by Rathbone and Robl (2001). Rathbone and Robl (2001) evaluated the relationship between ammonia in fly ash and the corresponding amount in air using laboratory and field-scale test methods:

$$NH_{3\text{ ash}} = \frac{(NH_{3\text{ water}})(\text{Water} - \text{to} - \text{Cement ratio})}{(\text{Fly Ash Content})}$$

The lab and field scale testing found allowable ammonia levels in the concrete water prior to setting (for 10 ppm in the air), to be approximately 50 mg/l for non-ventilated spaces and 75 mg/l for well ventilated spaces.

Fly ash from CCS is a desirable, high quality material and has been used extensively in North Dakota, Minnesota, Colorado, and as far away as California. In a review of fly ash uses in North Dakota, the Energy & Environmental Research Center (EERC) stated:

“NDDOT uses fly ash in almost all concrete projects at a replacement rate of 30%. A replacement rate between 15% and 30% is specified by most state DOTs (if they specify fly ash use at all), making NDDOT’s specification on the higher end compared to other states. For mass pours, a replacement rate of 40% is allowed and is more typical.” (EERC 2011)

Based on these uses of CCS fly ash, the above relationship was used to evaluate the maximum allowable ammonia content in fly ash for 15% and 30% fly ash mixtures, for water cement ratios between 30% and 40%, and for well-ventilated and non-ventilated areas. Results of the calculations are shown in Table 1 and Figure 1 below.

Table 1: Allowable Ammonia Content in Fly Ash

Condition	Ammonia in Air*	Water/Cement Ratio	Allowable Ammonia Content in Fly Ash (15% fly ash mixture)	Allowable Ammonia Content in Fly Ash (30% fly ash mixture)
	ppm		ppm	ppm
Ventilated	10	0.4	200	100
Non-Ventilated	10	0.4	133	67
Ventilated	10	0.3	150	75
Non-Ventilated	10	0.3	100	50

*Practical limit based on experience (Rathbone and Robl 2001)

Figure 1: Allowable Ammonia Content in Fly Ash

2.3 Marketability Conclusions

When ammoniated fly ash is used in concrete, the ammonia can be released into the air during placement and may cause irritation to individuals placing the concrete. The amount of ammonia released into the air is a function of fly ash content, the water/cement ratio of the concrete batch, and the ammonia concentration in the ash. Generally, industry experience indicates that fly ash used for concrete should have less than 100 ppm ammonia to prevent handling issues from limiting the marketability of the ash. Based on the use of CCS fly ash as a high percentage cement replacement (30%), a calculated allowable ammonia level in the fly ash may range between 50 ppm and 100 ppm. When discussing ash sales impacts at CCS, Sahu (2011) cites Larrimore (2002) in concluding that 2 ppm ammonia slip can result in 100 ppm ammonia in ash. According to Larrimore (2002), 4 ppm ammonia slip can result in 200 ppm ammonia in ash, a potentially unmarketable level of ammonia for use in ready mix. As previously stated, Fuel Tech indicated that ammonia slip between 5 ppm and 10 ppm is reasonable for CCS and that the ammonia adsorbed onto fly ash may range between 50 and 100 ppm under steady state conditions (slip and ammonia adsorbed onto fly ash would be higher during load swings or upset conditions). Because the ash marketer and ready-mix user may not know the exact use of fly ash when it is purchased and placed in a silo, the practical limit for CCS fly ash is 50 ppm or less to allow its use in a wide variety of applications.

Definitive information is not available for the levels of ammonia that will be present in the fly ash at CCS due to SNCR ammonia slip. However, review of available literature indicates a reasonably high probability that ammonia concentrations would be in the range that is problematic for marketers and end users of CCS fly ash. Therefore, it is prudent for engineering cost evaluations to assume ammonia levels in CCS fly ash will be higher than the acceptable ammonia levels for CCS fly ash destined for beneficial use, and therefore to assume that CCS fly ash will be disposed or will require treatment with ASM technology to be sold for beneficial use.

3.0 AMMONIA SLIP MITIGATION

3.1 Background

Boral has developed an ASM technology to manage ammonia levels in the fly ash, allowing a portion of the fly ash produced to be sold as a concrete additive. The Boral ASM technology was initially developed in 2001 with the first US patent issued in 2004. The first commercial installation of ASM technology was completed at RG&E Russell Station in Rochester, New York, in 2004. Russell Station used an SNCR and burned eastern bituminous coal. This power plant has since been closed and deconstructed.

The second commercial installation was performed at Eastlake Station in Ohio. Eastlake Station was a 600-megawatt (MW) unit that was fired with a 50/50 blend of Powder River Basin (PRB) and eastern bituminous coal while generating approximately 100,000 tons per year of fly ash during full operation. Headwaters (acquired by Boral in 2017) was able to blend, treat, and market approximately 85% of the fly ash produced at Eastlake Station. Fly ash was not treated during periods of highly variable ammonia concentrations, typically occurring during SNCR upset or plant load swings. This power plant is currently closed.

Boral is currently in the process of installing ASM technology at the Monroe Power Plant in Michigan and anticipates ASM system startup later in 2019. Monroe Power Plant has an SCR and the ASM plant is expected to run on demand rather than full time. The plant can burn petcoke, PRB, and eastern bituminous coals. The ASM system is designed to treat fly ash with ammonia concentrations up to between 150 and 200 ppm with a treated fly ash ammonia limit of 75 ppm or lower for sales.

Currently, there are no commercial applications of ASM technology at a lignite-fired power plant, and Boral has not conducted any research on the application of the technology to lignite-derived fly ash. Due to the lack of commercial experience with lignite-derived fly ash, Boral cannot provide a guarantee that the ASM technology can be successfully applied.

3.2 Process Description

The ASM technology mixes approximately 0.5-pound (lb) calcium hypochlorite (Cal-Hypo) with approximately 3,000-lb of fly ash in a hopper. The dose of Cal-Hypo, which is fed into the hopper using a rotary screw, is based on the ammonia concentration in the fly ash. The typical ammonia range for treatment is 50 to 150 ppm with a dosage of 0.2 to 1.3 lb of Cal-Hypo, resulting in ammonia concentrations following treatment of approximately 35 to 80 ppm. The dosage is affected by other potential chemical demands for Cal-Hypo depending on fly ash chemistry. Additional testing of CCS fly ash is required to confirm the effectiveness of Cal-Hypo and the appropriate dosage.

Golder visited the commercial application of ASM technology at Eastlake Station in 2011 at a time it was operational (Figure 2). Fly ash from the electrostatic precipitator (ESP) was sent to one of two fly ash silos where the fly ash was tested daily to determine ammonia concentrations (Figure 3). If the ammonia concentrations were above 150 ppm, the fly ash was diverted for disposal. Fly ash with ammonia concentrations less than 150 ppm were sent to a third silo, after which the fly ash was “dosed” with Cal-Hypo and sent to a fourth silo (Figure 4 through Figure 6). The SNCR at Eastlake could not keep the ammonia slip consistent, and often over-treated a portion of the fly ash stream. To increase the amount of treatable and marketable fly ash, fly ash with no ammonia from other sources was regularly blended into the Eastlake fly ash to keep the initial ammonia content below 150 ppm. Through the operation of the SNCR and by blending non-ammonia-impacted fly ash with Eastlake’s ammonia-impacted fly ash, Eastlake was able to market approximately 85% of the produced fly ash as this fly ash was considered “treatable” (i.e., ammonia concentration levels were below 150 ppm). Diagrams of the Eastlake Station system provided by Headwaters (Boral) are shown in Appendix A.

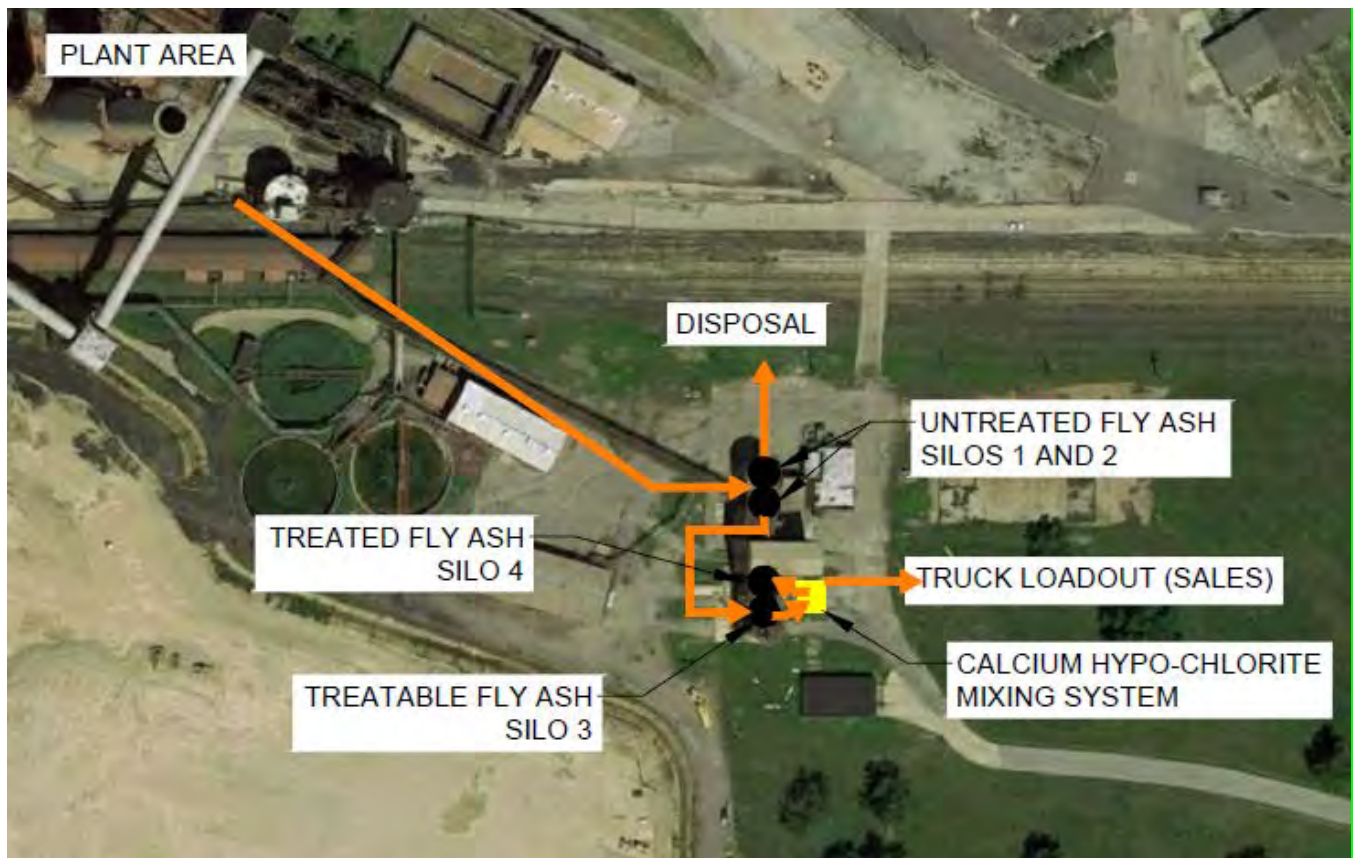

Figure 2: Eastlake Station ASM Layout

Figure 3: Eastlake Station ASM Lab

Figure 4: Eastlake Station Silo 3, Silo 4, and ASM System Location

Figure 5: Eastlake Station ASM Control Panel

Figure 6: Eastlake Station ASM Mixing Hopper

3.3 Design and Limitations

Based on the Eastlake Station application, ASM is applied to fly ash with ammonia concentration levels less than 150 ppm. Ammonia levels can fluctuate based on plant load variations and SNCR operation. Ammonia concentrations are more consistent at base load conditions and dosing levels are typically based on this condition. Therefore, during load “swings”, properly adjusting the amount of ammonia injected into the flue gas can be difficult, resulting in varying concentrations of ammonia in the fly ash. In the event of a plant upset condition, several days may pass until the fly ash is produced with ammonia concentrations at “treatable” levels. The concerns are two-fold. First, if the fly ash is not treated with enough Cal-Hypo, objectionable levels of ammonia will be released when the fly ash is mixed with water. Low concentrations of ammonia gas are an irritant, while high concentrations of ammonia gas can be dangerous to health. Second, if too much Cal-Hypo is added to the fly ash, chlorine gas will be released when the fly ash is mixed with water. Chlorine gas, even at low concentrations, is dangerous to health.

In addition to the impacts of load “swings” on the treatment effectiveness, Boral has indicated that the amount of fly ash produced at CCS may also cause issues. At Eastlake Station, the low production of fly ash allowed for significant time between fly ash being produced to fly ash being loaded for sales (fly ash could wait in silos, and trucks could wait to be loaded). This time allowed for testing of the untreated fly ash, dosage testing, and then full-scale dosage and testing. At CCS, approximately 1,500 tons of fly ash are produced daily and there are limits to fly ash storage and load-out rates for beneficial use and sales. Therefore, Boral has indicated that a robust quality assurance and quality control program would be required to understand the concentration of ammonia in the

untreated fly ash, the dosage rates, and the ammonia concentrations in the treated fly ash. In addition, the rate of production and load-out may cause some treated fly ash to be disposed rather than sold.

3.4 ASM Application at CCS

The application of ASM technology at CCS is being evaluated as an option for treating ammonia slip impacted fly ash to allow continued beneficial use and sale of fly ash.

3.4.1 Potential Design at CCS

For cost estimating, a potential layout for the application of ASM at CCS is shown in Figure 7. This potential layout utilizes the existing fly ash infrastructure including the truck load-out silos (Fly Ash Silos 91 and 92), the rail load-out silo (Rail Loadout Silo 93), and the fly ash storage dome (Fly Ash Dome 94). To use ASM technology, the layout adds a new truck load-out silo south of Silos 91 and 92 and adds ASM Cal-Hypo feed systems at both the new truck load-out silo and the existing rail load-out silo (Silo 93). The general flow of material is treatable fly ash being routed to either the new truck load-out silo, Fly Ash Dome 94, or the rail load-out silo. From these locations, the fly ash is tested and then mixed with Cal-Hypo while being loaded into the trucks or rail cars. Additional testing of the resultant product would also be performed. Fly ash that is expected not to be treatable or saleable is routed to the existing truck load-out Silos (Silos 91 and 92) where the fly ash will be loaded into haul trucks and disposed at on-site disposal facilities.

Figure 7: Coal Creek Station ASM Layout

As discussed in Section 3.2, not all fly ash coming from the precipitators is expected to have “treatable” concentrations of ammonia. Generally, when the power generation units are operating at steady load and the SNCR ammonia injection system is operating properly, the produced fly ash should be “treatable” using the ASM system and will be collected in Rail Loadout Silo 93, Fly Ash Dome 94, or the new truck loadout silo. Conditions under which the ammonia content of the produced fly ash will be questionable include:

- Unit load swings causing variations in ash ammonia concentrations (load swings may be due to regional wind penetration or variable load consistent with MISO);
- SNCR ammonia injection feed system problems; and
- Unit startup and shutdown resulting in oily ash.

Golder anticipates that when any of these conditions occur, the produced fly ash will automatically be directed to Fly Ash Silos 91 and 92 for disposal. Fly ash will not be directed to Rail Loadout Silo 93, Fly Ash Dome 94, or the new truck loadout silo for sale of the fly ash until the upset condition is over and the fly ash collected in the first two rows of the electrostatic precipitator (ESP) has been tested and proven to contain less than 150 ppm of ammonia.

Currently, approximately 80% of the fly ash produced annually at CCS is sold. The remaining 20% is disposed due to market conditions, storage/transportation issues, and unit startup and shutdown resulting in oily ash. Based on a review of the recent and anticipated load profile at CCS, and concerns described by Boral in operating ASM technology on the amount of fly ash produced at CCS, an additional 20% of the fly ash produced annually is expected to be disposed due to ammonia concentrations which will make the fly ash untreatable or unmarketable after treatment.

3.5 Cost Estimate

Included in the cost estimate are costs for the ASM infrastructure, including engineering and design, construction, and operations and maintenance. Golder used actual costs from similar projects and professional judgement to develop this cost estimate. Sources and assumptions are documented where appropriate. Some general assumptions for the cost estimate include:

- All costs are estimated in 2019 dollars.
- Capital costs are annualized based on a 20-year life and 5.25% interest rate.
- Existing fly ash sales infrastructure (silos, scales, and rail facilities) and operations and maintenance thereof are not included.

3.5.1 System Engineering and Design

Costs for system engineering, design, and permitting are estimated at 10% of the total construction costs to develop new facilities, based on Golder’s professional judgement.

3.5.2 New Truck Load-Out Silo

The costs for the new truck load-out silo include site preparation, permit application, silo and handling equipment, dust collection equipment, and feed piping. Costs for this construction are based on the construction of a similar fly ash sales terminal constructed for GRE in 2003. This silo had a 5,000-ton capacity and was used to transfer fly

ash from rail cars to trucks (Figure 8). The total estimated cost for this item is \$2.02 million (in 2019 dollars) and includes the following:

- Silo and truck scale similar to the Irondale, CO unit:
 - Silo slab on grade;
 - Starvac reclaimer;
 - Truck scale beside the silo on grade;
 - Screw conveyor from discharge of the Starvac reclaimer;
 - Bucket elevator to overhead;
 - Air slide; and
 - Building with the scale and ASM controls.
- Additional items needed at CCS:
 - Feed piping and valves from each of the four fly ash conveying lines; and
 - Higher capacity dust collectors to handle the high air flow from the ESP.

Details for this cost estimate are included in Appendix B.

Figure 8: Typical Silo used in Cost Estimate

3.5.3 Cal-Hypo Feed System

The costs for the Cal-Hypo feed systems are estimated at \$680,000 (in 2019 dollars) and include:

- Rail Loadout Silo 93:
 - Cal-Hypo storage and conveying building;
 - Day storage hopper for Cal-Hypo on the silo weigh bin floor;
 - Conveying system from the storage building to the day storage hopper;
 - Variable speed screw conveyor to feed Cal-Hypo into existing weigh hopper;
 - ASM system controls.
- New truck loadout silo:
 - Weigh hopper above truck loadout spot;
 - Cal-Hypo storage and conveying building;
 - Day storage hopper for Cal-Hypo on the silo weight bin floor;
 - Conveying system from the storage building to the day storage hopper;
 - Variable speed screw conveyor to feed Cal-Hypo into existing weight hopper;
 - ASM system controls.

3.5.4 GRE Internal Costs

Internal costs for GRE to manage consultants, contractors, and in-house staff is estimated at 10% of the total costs (construction, engineering, permitting, and CQA), based on GRE's experiences with projects at CCS.

3.5.5 Project Contingency

Due to the order-of-magnitude scope of this cost estimate, a contingency of 20% on the construction costs was added to the cost estimate.

3.5.6 Operational and Maintenance Costs

ASM post-processing operations and maintenance costs are estimated as an annual cost. Operations costs include the cost of Cal-Hypo, fly ash sampling and testing costs, and labor to operate the system. Maintenance costs include labor and materials to maintain and repair the added equipment at Rail Loadout Silo 93 and the new truck loadout silo.

The estimated cost for this item, based on annual sale/processing of 308,000 tons, is approximately \$1.67 million per year. Details for this cost estimate are included in Appendix B.

3.6 ASM Post-Processing Cost Summary

Using the quantities and the unit pricing described above, ASM post-processing costs are estimated as \$6.40 per ton of fly ash treated.

4.0 FLY ASH DISPOSAL

Fly ash that cannot be marketed for beneficial use is disposed in engineered and permitted facilities at CCS. Golder has prepared this order-of-magnitude cost estimate to compare costs between three scenarios defined to assess the potential impact of an SNCR on fly ash sales and disposal at CCS. Summary costs and key inputs are included in Table 2 through Table 4 and Figure 9 through Figure 11, with cost estimate details provided in Appendix B.

4.1 Fly Ash Disposal Scenarios

Three scenarios were evaluated to estimate the annual cost and the cost per ton to dispose fly ash at CCS. These scenarios are as follows:

- Scenario A – This scenario is the base case, with fly ash sales equal to the average fly ash sales at CCS between 2014 and 2018 (approximately 80% of fly ash produced). The scenario assumes that fly ash will be disposed in a new landfill with a design based on EPA CCR Rules with a 20-year disposal capacity. No post-processing of the fly ash is required to make it marketable.
- Scenario B – This scenario assumes that the ammonia slip impact of an SNCR makes fly ash at CCS unsalable. The scenario also assumes that fly ash will be disposed in a new landfill with a design based on EPA CCR Rules with a 20-year disposal capacity.
- Scenario C – This scenario assumes that Boral's ASM technology will be viable for ammonia-impacted fly ash at CCS. However, sales will be reduced from current sales due to load swings, outages, ASM system upsets, market conditions, and other factors previously identified within this report (assume 60% of fly ash produced can be sold). The scenario also assumes that fly ash will be disposed in a new landfill with a design based on EPA CCR Rules with a 20-year disposal capacity.

A summary of the fly ash production, sales, and disposal annual tonnages for these scenarios is provided in Table 2.

Table 2: Fly Ash Sales and Disposal Tons

	Scenario A (Current Sales)	Scenario B (No Sales)	Scenario C (Reduced Sales & ASM)
Fly Ash Produced (tons/year)	513,000	513,000	513,000
Fly Ash Sold (tons/year)	400,000	0	308,000
Fly Ash Disposed (tons/year)	113,000	513,000	205,000

The total tonnage of fly ash produced is variable based on items such as plant load, plant efficiency, coal quality, and coal processing. Tonnage used in this analysis is an average of the actual tonnage produced, sold, and disposed at CCS between 2014 and 2018.

4.2 Landfill Design

For all three scenarios a 20-year disposal capacity and a design in accordance with EPA CCR Rules is assumed. Further, the landfill is assumed to be built on property not currently owned by GRE. This cost estimate assumes that property just south of the plant property would be purchased for the new facility. Figure 9 shows a potential location for these new facilities just south of the plant property and represents the approximate footprint required for Scenario C.

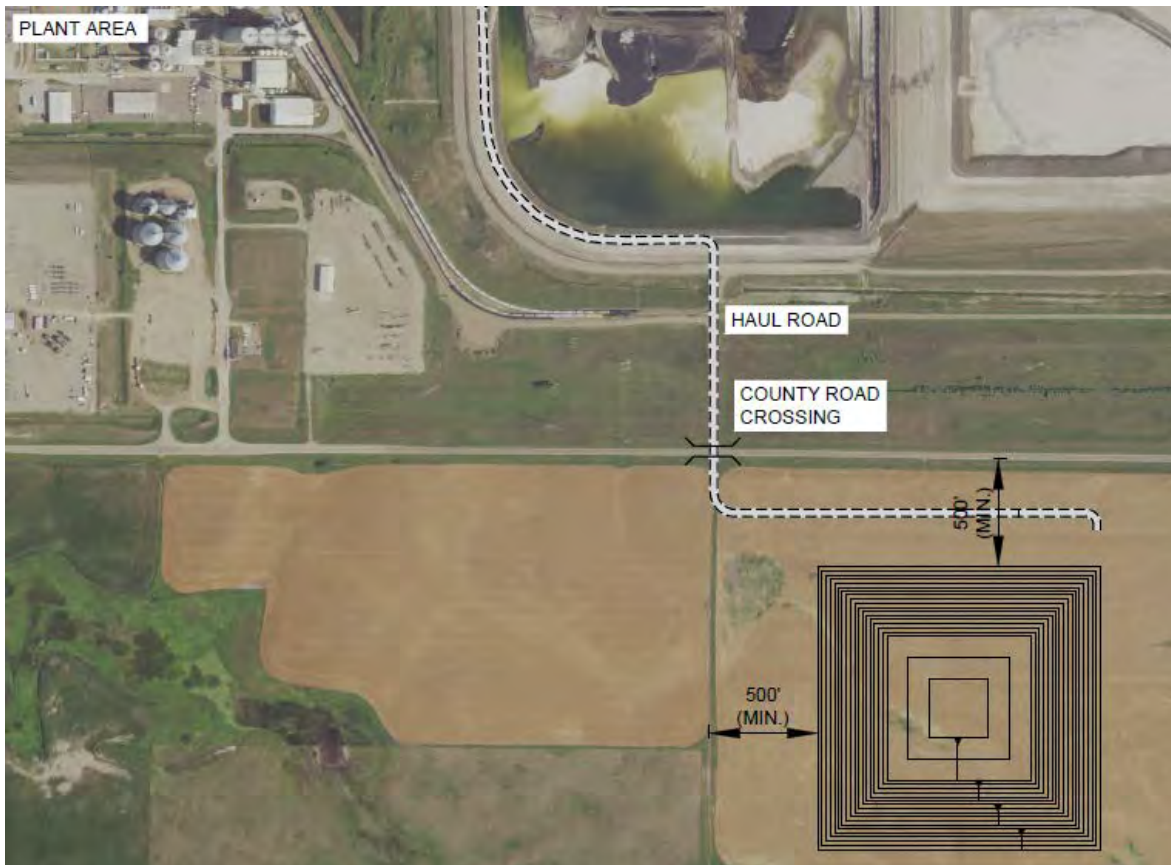

Figure 9: Potential Landfill Location (Scenario C)

4.2.1 Landfill Size

Landfill size is based on a 20-year fly ash disposal capacity. For the three scenarios, size varies between 2.3 million and 10.3 million tons of capacity. For each scenario, Golder developed a simplified landfill footprint that would provide the 20-year fly ash disposal capacity. The simplified landfill design assumes 10 feet of cut, a 12-foot high soil perimeter berm, 3H:1V soil berm slopes, and 4H:1V fly ash slopes with a 5% crown. Based on preliminary engineering, the landfill capacity ranges between 80,000 and 120,000 cubic yards (cy) per lined acre due to the increased height capacity of a larger footprint facility. Figures showing the approximate size of each scenario are included in Appendix B.

The amount of cover area in relationship to the liner area has also been estimated based on preliminary engineering as 1.1 acres of cover for every 1 acre of liner.

The amount of land required is assumed to encompass at least a 500-foot buffer beyond the lined footprint to allow for access roads, fencing, support structures, and groundwater monitoring. For the land acquisition purchase estimate, the nearest eighth section of land to the required footprint was assumed.

Table 3 provides a summary of the estimated facility liner area, cover area, and site area for the three scenarios.

Table 3: Scenario Landfill Sizes

	Scenario A (Current Sales)	Scenario B (No Sales)	Scenario C (Reduced Sales & ASM)
Liner Area (acres)	24.5	72.0	36.5
Cover Area (acres)	27.0	79.0	40.0
Site Area (acres)	160	240	160

4.2.2 Infrastructure Development

Since the landfill would be constructed on new property, considerable site development is required. Such site development may include:

- Haul truck access road;
- Fencing and gates around the property;
- Power to the new site;
- Monitoring wells upgradient and downgradient of the facility; and
- Water return pipeline to allow for pumping of excess contact water from the site to the ash water tanks within the plant.

Additionally, haul trucks will be required to cross a county road to deliver fly ash from the plant to the new facility. For safety and operational flexibility, a new county road bridge should be constructed to allow haul truck traffic to pass under the county road. This bridge would include the bridge structure as well as the grading and embankment costs associated with the approach on the county road.

4.2.3 Liner

A liner design is based on EPA CCR Rules. The assumed liner system is shown in Figure 10 and consists of (from bottom to top) a compacted clay liner (1×10^{-7} centimeters per second, cm/sec, maximum permeability), a geomembrane, a leachate collection layer consisting of drainage material, piping and sumps, and a protective cover layer.

Figure 10: Composite Liner Detail

4.2.4 Cover

The final cover design is also based on EPA CCR Rules. The assumed cover system is shown in Figure 11 and consists of (from bottom to top) a leveling fill layer, a compacted clay liner (1×10^{-7} cm/sec maximum permeability), a geomembrane, a drainage layer consisting of drainage material and piping, and a vegetation layer. The drainage layer over the geomembrane is required to control the head on the liner and the resulting stability of growth medium. Additionally, the cover will use terrace channels and armored down-chute channels to manage surface water runoff and reduce erosion.

Figure 11: Composite Cover Detail

4.3 Cost Estimate

The cost estimate includes costs for the life of the disposal facility including engineering, design and permitting, construction, and operations and maintenance, including closure and post-closure care. Golder used actual costs from similar projects at CCS, crew analyses based on local contractor rates, RS Means manuals (RS Means 2019), and professional judgement to develop this cost estimate. Sources and assumptions are documented. Some general assumptions for the cost estimate include:

- All costs are estimated in 2019 dollars.
- Capital costs are annualized based on a 20-year life and 5.25% interest rate.
- Existing fly ash processing equipment (silos, unloaders, etc.) is not included. Disposal costs begin once the haul trucks are loaded with fly ash.
- Existing fly ash sales infrastructure (silos, scales, rail facilities) and operations and maintenance thereof are not included.
- Disposal costs only include fly ash disposal and not facility airspace or operations and maintenance costs for other CCRs produced at CCS.

4.3.1 Engineering, Design, and Permitting

Costs for engineering, design, and permitting are estimated at 10% of the total construction costs to develop new facilities, based on Golder's experience with coal combustion residuals facilities in the Midwest. The components included in this cost may include a facility siting evaluation, design of the facility, submittal of a solid waste landfill

permit and associated permit renewals, submittal of air permits and NPDES permits, and creation of construction and bid packages for the facility.

The siting evaluation may include a hydrogeological characterization of the site, including drilling, soil testing, establishing groundwater baseline data, and preparing a hydrogeologic characterization report. Additional siting efforts may include a wetlands delineation, a site topographic survey, and other evaluations as required.

Facility design includes both landfill design and infrastructure design, including grading plans, deposition plans, contact and surface water management plans, design of haul roads, and design of the county road bridge crossing.

Permitting may include the solid waste landfill permit, air permits, and an NPDES permit, including the development of operations plans for the facility, closure plans, post-closure care plans, groundwater sampling and analysis plans, a Stormwater Pollution Prevention (SWPP) plan, and other required submittals associated with the construction and operation of a new fly ash disposal facility.

4.3.2 Land Acquisition

Land acquisition of the property required for the new facility includes site due diligence and property purchase. Site due diligence may include survey, geotechnical characterization, environmental audit, and a landfill siting suitability evaluation. The property purchase may include legal fees as well as the purchase price of the property. Currently, crop land near CCS is selling for \$3,000 to \$5,000 per acre. A unit cost of \$4,000 per acre is used in the analysis to account for both the cost of the land and the site due diligence.

4.3.3 Infrastructure Development

The costs for infrastructure development include fencing, monitoring well installation, power from the plant to the landfill, facility access haul road, a return water pipeline, and a county road bridge crossing. The costs for this construction are estimated to be between \$2,740,000 and \$2,910,000 for the various scenarios. Details for the quantities and unit rates applied to this work are included in Appendix B.

4.3.4 Liner Construction

Liner construction includes several elements as described above, including a compacted clay liner, a geomembrane layer, a leachate collection system, and protective cover. Additionally, the construction effort will include clearing and grubbing, topsoil stripping and stockpiling, construction of temporary roads, soil excavation and stockpiling to be used for perimeter berms, compaction of the liner and cover, and application of site controls such as erosion controls. The costs for construction are estimated to be between \$239,000 and \$243,000 per acre for the different scenarios. Details for the quantities and unit rates applied to this work are included in Appendix B.

4.3.5 Final Cover Construction

Final cover construction includes leveling fill, a compacted soil layer, a geomembrane liner, a drainage collection system, growth medium, topsoil, armored down-chute channels, and vegetation of the site. Costs for this construction are estimated to be between \$183,000 and \$201,000 per acre for the different scenarios. Details for the quantities and unit rates applied to this work are included in Appendix B.

4.3.6 Post-Closure Care

Post-closure care includes groundwater monitoring and reporting (for the state and the EPA CCR Rule), annual site inspections, additional compliance requirements associated with the EPA CCR Rule, repair and maintenance of the final cover (soil, seeding, mowing, surface water structures), maintenance of the facility access roads and fencing, and permit-required record keeping. Post-closure care will occur for 30 years following the closure of the facility and is included in the capital/direct costs for this cost analysis. Costs for post-closure care are estimated to be between \$106,000 and \$154,000 per year for the different scenarios. Details for the quantities and unit rates applied to this work are included in Appendix B.

4.3.7 Construction Management and Construction Quality Assurance

Throughout the construction effort, a construction manager will be on-site to communicate between the contractors and the design engineer. In addition to the construction manager, one or several construction quality assurance (CQA) monitors will be on-site during the construction. Costs for construction management and construction quality assurance are estimated as 10% of the total construction costs to develop the facility, based on Golder's experience with coal combustion residuals facilities in the Midwest.

4.3.8 GRE Internal Costs

Internal costs for GRE to manage consultants, contractors, and in-house staff are estimated at 10% of the total costs (construction, engineering, permitting, CQA), based on GRE's experience with projects at CCS.

4.3.9 Project Contingency

Due to the order-of-magnitude scope of this cost estimate and the associated engineering and unit rate development, a contingency of 20% on the construction and land acquisition costs was added.

4.3.10 Operational Costs

Landfill operations and maintenance costs are estimated as an annual cost and include both engineering support and site operations. Engineering support includes design support, permit support, an annual inspection, groundwater monitoring and reporting (for the state and the EPA CCR Rule), additional compliance requirements associated with the EPA CCR Rule, and an annual survey. Site operations include the ownership and operation of site haul and placement equipment, full-time site staff, and material expenses. Since ammonia concentrations in the fly ash to be contained in site landfills may be an irritant, operational modifications may be required to handling and placement methods. Costs associated with these potential operational changes have not been included.

Estimated costs for this work are broken into haul costs, placement costs, and site management and maintenance costs.

Haul costs were estimated at \$3.30 per ton based on haul distance, equipment capacity, operator costs, and equipment costs. Placement costs were estimated at \$2.30 per ton based on dozer spreading with minimal compaction. Details on the haul and placement costs are included in Appendix B.

Site management and maintenance costs were estimated between \$196,000 and \$396,000 per year for the different scenarios. Details on the annual site management and maintenance costs are included in Appendix B.

4.4 Disposal Cost Summary

Using the quantities and the unit pricing described above, disposal costs were estimated for the three scenarios and are summarized in Table 4.

Table 4: Disposal Cost Summary

	Scenario A (Current Sales)	Scenario B (No Sales)	Scenario C (Reduced Sales & ASM)
Fly Ash Disposal (ton/year)	113,000	513,000	205,000
Disposal Cost (\$/ton)	\$26.00	\$15.80	\$20.60
Annual Disposal Cost (\$/year)	\$2,940,000	\$8,100,000	\$4,220,000
Annual Increase in Disposal Cost Compared to Scenario A (\$/year)	-	\$5,160,000	\$1,280,000

The disposal cost per ton is reduced with increased disposal quantity due to the efficiency of the landfill footprint (a larger landfill can be built higher and has larger capacity), and the distribution of fixed costs (roads, bridge, fence) across a larger amount of disposed fly ash.

Based on the annual disposal cost estimate, the potential impact of an SNCR to the fly ash disposal costs at CCS may be an additional \$5.2 million per year if fly ash is no longer marketable or an additional \$1.3 million per year if the ASM technology proves successful.

4.5 Industry Ranges for CCR Disposal

Disposal costs of \$16 to \$26 per ton were estimated based on site-specific designs for the disposal of fly ash at CCS. These disposal costs were based on a detailed engineering cost estimate for CCS including costs from landfill development to post-closure care.

In 2010, the EPA estimated baseline (i.e. current) CCR disposal costs in their Regulatory Impact Analysis for EPA's Proposed RCRA Regulation of Coal Combustion Residuals Generated by the Electric Utility Industry (EPA 2010). In Chapter 3 of that report, the EPA provided a cost estimate for the management of CCRs and estimated a range of \$2 per ton to \$80 per ton with an average of \$59 per ton. In discussion of these results, the report indicates that \$2 per ton is reflective of unlined, near-plant impoundments in states with low regulatory requirements, and the high end of \$80 per ton is reflective of off-site commercial disposal in landfills. The proposed fly ash disposal facilities at CCS are composite-lined (per EPA rule requirements), engineered landfills located at varying distances from the plant.

The EPA report further references information from the American Coal Ash Association (ACAA) to validate its cost estimate. The ACAA routinely collects ash disposal and beneficial use information from its members and has developed estimates for the disposal of CCPs. From the ACAA website and referenced in the EPA report:

“As one can see, a variety of factors enter into determining disposal costs. The lowest cost occurs when a disposal site is located near the power plant and the material being disposed can be easily handled. If the material can be piped, rather than trucked, costs are usually lower. In these types of situations, cost may be as low as \$3.00 to \$5.00 per ton. In other areas, when distance is far away and the material must be handled several times due to its moisture content or volume, costs could range from \$20.00 to \$40.00 a ton. In some areas, the costs are even higher. If new sites are required and extensive permitting processes take place, the total cost of the facility may be increased, resulting in higher disposal costs over time.” (ACAA 2012)

The disposal of fly ash at CCS does not fall at either cost extreme (unlined impoundment or off-site commercial disposal), and the engineering estimate of \$16 to \$26 per ton appears well within the EPA’s cost estimate and industry practice (particularly when accounting for inflation and new regulatory requirements since the 2010 estimates).

5.0 COST IMPACT

The total cost impact of an SNCR on fly ash management at CCS requires the aggregation of the post-processing costs (ASM), the disposal costs, and the loss in revenue generated from the sale of fly ash. This total cost impact was evaluated for the three Scenarios discussed previously. As a basis for the cost comparison, Table 5 provides a summary of the annual tons of fly ash produced, sold, disposed, and the loss in fly ash sales in comparison to Scenario A (current sales).

Table 5: Fly Ash Sales and Disposal Tons

	Scenario A (Current Sales)	Scenario B (No Sales)	Scenario C (Reduced Sales & ASM)
Fly Ash Produced (tons/year)	513,000	513,000	513,000
Fly Ash Sold (tons/year)	400,000	0	308,000
Fly Ash Disposed (tons/year)	113,000	513,000	205,000
Lost Fly Ash Sales (tons/year)	0	400,000	92,000

5.1 Ammonia Slip Mitigation

Post-processing of ammonia slip impacted fly ash by Boral’s ASM technology is proposed as an option to maintain fly ash sales. This post-processing is only being applied to the sold fly ash tonnage in Scenario C. Depending on the plant power profile and how the fly ash distribution system is set up, additional tons of fly ash will likely be treated and disposed, but these potential cost impacts are not included. The cost impact for ASM post-processing is shown in Table 6.

Table 6: ASM Post-Processing Costs

	Scenario A (Current Sales)	Scenario B (No Sales)	Scenario C (Reduced Sales & ASM)
ASM Unit Rate Capital and O&M (\$/ton sold)	\$0.00	\$0.00	\$6.40
ASM Annual Capital and O&M (\$/year)	\$0	\$0	\$1,980,000

5.2 Fly Ash Disposal

Disposal costs vary between the scenarios with the per ton cost being reduced by disposal volume. The cost impact for fly ash disposal is shown in Table 7.

Table 7: Fly Ash Disposal Costs

	Scenario A (Current Sales)	Scenario B (No Sales)	Scenario C (Reduced Sales & ASM)
Unit Rate Capital and O&M (\$/ton disposed)	\$26.00	\$15.80	\$20.60
Annual Capital and O&M (\$/year)	\$2,940,000	\$8,100,000	\$4,220,000

5.3 Lost Sales

The current fly ash sales are supported by a large investment in capital infrastructure as well as a large operations and management contingency. Changes to the quantity of fly ash marketed and sold will have a direct impact on fly ash management costs, as the revenue currently used to offset fly ash management will be lost. The lost fly ash sales revenue to GRE is based on the 2014 to 2018 average revenue per ton of \$12.40. The cost impact of the potential loss in fly ash sales is shown in Table 8.

Table 8: Cost Impact of Lost Fly Ash Sales

	Scenario A (Current Sales)	Scenario B (No Sales)	Scenario C (Reduced Sales & ASM)
Lost Fly Ash Sales Revenue (\$/ton lost sales)	\$12.40	\$12.40	\$12.40
Annual Lost Fly Ash Sales Revenue (\$/year)	\$0	\$4,960,000	\$1,140,000

5.4 Combined Impact to Fly Ash Management

The combination of the ASM post-processing, fly ash disposal, and lost fly ash sales revenue is shown in Table 9. This table also shows the additional cost impact of Scenario B and Scenario C in comparison with the current sales (Scenario A).

Table 9: Total Fly Ash Management Costs

	Scenario A (Current Sales)	Scenario B (No Sales)	Scenario C (Reduced Sales & ASM)
Total (Disposal + Post-Processing + Lost Sales)			
Annual Cost (\$/year)	\$2,940,000	\$13,060,000	\$7,340,000
Unit Cost (\$/ton produced)	\$5.70	\$25.50	\$14.30
Additional Cost (Scenario B/C – Scenario A)			
Fly Ash Management Cost (\$/year)	-	\$10,120,000	\$4,400,000
Fly Ash Management Cost (\$/ton produced)	-	\$19.70	\$8.60

The total additional cost impact to fly ash management as a result of an SNCR is estimated between \$4.4 and \$10.1 million per year.

6.0 CLOSING

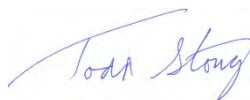

We appreciate the opportunity to provide this third-party review of Boral's ASM technology, and an estimate of the potential impact of SNCR on fly ash management costs including disposal and sales. Please contact us if you have any questions about the information provided.

Fly Ash Management Impact Evaluation Summary (March 1, 2019)

	Scenario A	Scenario B	Scenario C
	Current fly ash sales with new EPA CCR Rule landfill	No fly ash sales with new EPA CCR Rule landfill	ASM technology to allow reduced fly ash sales with new EPA CCR Rule landfill
Fly Ash Quantities			
Fly Ash production (ton/yr)	513,000	513,000	513,000
Fly Ash Sales (ton/yr)	400,000	0	308,000
Fly Ash Disposal (ton/yr)	113,000	513,000	205,000
Lost Fly Ash Sales (ton/yr)	0	400,000	92,000
ASM Fly Ash Post Processing			
ASM Unit Rate Capital and O&M (\$/ton sold)	\$ -	\$ -	\$ 6.40
ASM Annual Capital and O&M (\$/yr)	\$ -	\$ -	\$ 1,980,000
Fly Ash Disposal			
Lined Footprint (acres)	24.5	72.0	36.5
Unit Rate Capital and O&M (\$/ton disposed)	\$ 26.00	\$ 15.80	\$ 20.60
Annual Capital and O&M (\$/yr)	\$ 2,940,000	\$ 8,100,000	\$ 4,220,000
Lost Fly Ash Sales			
Lost Fly Ash Sales Revenue (\$/ton lost sales)	\$ 12.40	\$ 12.40	\$ 12.40
Annual Lost Fly Ash Sales Revenue (\$/yr)	\$ -	\$ 4,960,000	\$ 1,140,000
Total (Disposal + Post Processing + Lost Sales)			
Annual Cost (\$/yr)	\$ 2,940,000	\$ 13,060,000	\$ 7,340,000
Unit Cost (\$/ton produced)	\$ 5.70	\$ 25.50	\$ 14.30
Additional Cost (Scenario B/C - Scenario A)			
Fly Ash Management Cost (\$/yr)	-	\$ 10,120,000	\$ 4,400,000
Fly Ash Management Cost (\$/ton produced)	-	\$ 19.70	\$ 8.60

Notes:

Capital costs annualized based on 20-year life and 5.25% interest rate.

Disposal costs based on new facility built across county road from Coal Creek Station with 20-year life.

EPA CCR Rule compliant facility (composite liner, leachate collection system, and composite cover).

Disposal costs only include fly ash disposal and not facility airspace or O&M for other CCPs.

Ammonia slip mitigation costs based on existing facility site visit and historic costs for fly ash infrastructure.

All costs are in 2019 dollars.

Lost fly ash sales revenue based on average per ton revenue to GRE between 2014 and 2018.

Existing fly ash sales infrastructure and O&M costs are not included.

Scenario A - Current Sales

Sizing Information

Annual Fly Ash Disposal	113,000	tn

Report "Ammonia Slip Mitigation for SNCR Impacted Ash at the Coal Creek Station" March 22, 2019; Boral Resources

March 22, 2019

Ammonia Slip Mitigation for SNCR Impacted Ash at the Coal Creek Station

Introduction

The contamination of fly ash with ammonia is a major concern for the marketability of ash for beneficial use in concrete. Although, ammoniated fly ash causes no detrimental effects to the durability of concrete, it poses safety concerns for workers pouring, placing and finishing fresh concrete. When placed in the high alkaline concrete slurry, ammoniated fly ash creates unpleasant and noxious ammonia gas odor that impacts the workers handling fresh concrete and concrete products. Exposure to ammonia in high concentrations is considered a health hazard to concrete workers as it can irritate or burn skin, mouth, throat, lungs and eyes. In very high dosages, ammonia gas can damage lungs or cause death. The presence of ammonia in ash at coal-fired plants and their disposal facilities can also create the potential for exposing power plant workers to this noxious gas. It also creates the potential for its release to air and water.

Ammonia in Ash from SNCR Systems

Ammonia-based environmental control technologies such as SCR and SNCR's are used to reduce NOx emissions from coal-fired power units. Ammonia/NOx redox reactions are not 100% complete and result in excess ammonia in flue gas. The excess ammonia gas, known as ammonia slip, reacts with other flue gas species, primarily SO₃, to form an ammonium salt solid deposit (NH₄SO₃) that is collected with the fly ash. The ammonium salt content of the ash depends on the ammonia slip, the SO₃ levels and other flue gas parameters such as acidity, temperature, etc. Typically, SNCR units have resulted in higher levels of ammonia in ash than SCR units.

A study performed by EPRI in 2007 reviewed eight units fueled with PRB/eastern bituminous coal blends where SNCRs systems had been installed and were in operation. The units were small and had ammonia slip up to 5 ppm. Four of the units had ammonia in the fly ash data ranging from less than 100 ppm to over 200 ppm. (EPRI 2007). Other studies suggest that 2 ppm ammonia slip may result in fly ash ammonia levels from less than 50 to several hundred mg/kg (Murarka 2003, Bittner 2001, Hinton 2012, Larrimore 2002). There is no published information for SNCR ammonia gas slip levels from lignite powered units.

For the Coal Creek units, Fuel Tech is quoting ammonia in ash levels at less than 20 mg/kg for 2 ppm slip and less than 100 mg/kg for 10 ppm slip for full load steady state operations. These estimated ammonia-in-ash levels relative to slip in flue gas do not correspond to literature values. In fact, the chart included herein, created by Larrimore (2002) and based on literature reviews and operating plant data, indicates that ammonia slip levels of 2 ppm can lead up to 100 mg/kg of ammonia in ash while a slip of 10 ppm could lead up to 500 mg/kg making the ash “unmarketable” for use in ready mix concrete.

The ammonia slip level from SNCR systems is highly dependent on the ammonia injection rate, NO_x reduction efficiency, plant load, reaction zone temperature and other unit specific flue gas parameters. Although the coal fired units at the Coal Creek station were designed for baseload service, they are expected to cycle depending on electric power demand and economic dispatch. Load cycling which includes ramping up or down and heat-up and cool-down of the units impart significant variability to the performance of the reaction-temperature sensitive SNCR. Load cycling is expected to result in significant variability in ammonia slip and ammonia in ash levels. Accurate and reliable ammonia slip and ash contamination levels can only be determined by a full scale SNCR demonstration and modeling of the specific fuel/unit.

Acceptable Levels of Ammonia in Ash

The ammonium salt present in the ash is rapidly converted to ammonia gas once the ash is exposed to the high pH concrete mixture. Ammonium salts are converted to ammonia gas at high pH (>10). Concrete mixtures can easily reach a pH of 12-13 within seconds of adding water to hydrate the cement. Mixing of concrete containing ammoniated ash will result in ammonia gas evolution from the mixer and during concrete pouring, placing and finishing. Ammonia gas evolution continues after placement of fresh concrete. Undesirable ammonia odor can linger after the hardening of concrete products in enclosed applications.

Exposure to ammonia gas evolving from concrete mixers or job sites is a health and safety risk. Exposure to mild levels of ammonia odors can generate unpleasant conditions for concrete workers that can result in undesirable finish and poor workmanship. The presence of even milder ammonia odor in residential/commercial concrete (indoor walls or slabs) would expose concrete producers, contractors, fly ash marketers and source utilities to potential product quality and health risk claims. Such claims of “poor” quality or potential long risk exposure from mild unpleasant odors would significantly impact ash sales in residential concrete markets.

There is no definitive ammonia limit for fly ash used in concrete since the factors affecting workers exposure are highly dependent on the amount of ash used in concrete and the environment where fly ash concrete is produced, placed and finished. When ammoniated fly ash concrete is placed in an open environment, personnel are rarely subjected to a time-weighted-average-permissible exposure limit exceeding 50 ppm if the ammonia in ash is less than 100 mg/kg. However, in a closed environment with restricted ventilation the same ammonia in ash level can result in exceeding both OSHA and NIOSH time-weighted-average-permissible exposure limits 50 ppm/20 ppm respectively. (Schert 2013)

Based on studies from the University of Kentucky funded by DOE, Electric Power Research Institute (EPRI) suggests the recommended limit of NH_3 is 200 mg/kg for fly ash used in concrete placed in well vented areas, in non-vented areas, the recommended limit is 100 mg/kg (Rathbone 2003). These limits are based on 15% ash replacement of cement, which is typical for ash derived from the combustion of eastern bituminous coal. When doubling the fly ash replacement to 30%, which is common with high quality ash such as the Coal Creek ash, the allowable ammonia content in fly ash will need to be reduced by 50% to 100 mg/kg and 50 mg/kg, respectively.

FDOT and other state agencies have concluded, if specifications are needed, an upper limit of 100 mg/kg would be protective of human health for most situations, and achievable under most circumstances (Schert 2012). It is Boral Resources policy to reject fly ash containing more than 100 mg/kg. However, fly ash products are marketed for use in various concrete products and applications. The amount of ash used in a concrete mixture also varies depending on the ash pozzolanic reactivity, specified concrete mixture, ambient temperature and other concrete product parameters.

Boral Resources and its concrete-producing customers do not know the intended application of all concrete products or the environment where the concrete is placed. Ammonia in ash contents of less than 100 mg/kg are sometimes requested by customers for the purpose of protecting their workers environment or to reduce the risk of customers' claims. Boral Resources complies with special customers request and periodically notifies customers with NH_3 in ash tests

results. Although, the 100 mg/kg threshold has been established based on research and general practice, in some ash markets such as MI/OH, Boral had to lower acceptable ammonia concentration to 75 mg/kg based on market feedback and customers' requests (concrete producers).

Rejected fly ash contaminated with unacceptable levels of ammonia is typically discarded in the landfill. Risks associated with the release and exposure at the utility fly ash landfill and handling systems are discussed elsewhere.

Economic impact of ammoniated ash

The direct cost impacts resulting from ammoniated ash include: lost revenue to GRE from fly ash sales by Boral, incremental ash disposal costs and the costs of long-term monitoring associated with the disposed ash. The direct cost impacts are discussed elsewhere. Other economic impacts include externalities of lost opportunity values related to; carbon emissions offset, additional sustainability benefits of reduced cement content Concrete durability benefits for using fly ash.

The Environmental impact of carbon emissions offset equal to 0.72 metric tons of avoided CO₂ equivalent emissions per ton of ash replacing cement in concrete. This is based on U.S. Environmental Protection Agency Report to Congress EPA530-R-08-007, June 3, 2008, page 3-11. Assuming potential future adoption of an accessible carbon tax or cap and trade program, the monetary value of carbon offsets is \$16.30 per ton. This value is based on California Carbon Allowance Futures pricing on January 15, 2019, for 2018 vintage offsets deliverable December 2019. Based on the same EPA Report to Congress, the other sustainability benefits of using fly ash to replace cement in concrete include; reduced water use by 379 liters per ton of ash and reduced energy consumption by 4,695 megajoules per ton of ash.

The benefits of fly ash use in concrete include; increasing higher ultimate strength, reducing permeability and corrosion of embedded steel, mitigating deleterious alkali aggregate reactions and increase concrete resistance to sulfate and other chemical attacks.

The Economic Impacts of Prohibiting Coal Fly Ash Use in Transportation Infrastructure Construction was evaluated by the American Road and Transportation Builders Association. Based on their September 2011 report, the economic impact of durability was estimated at \$478 per ton of ash replacing cement in concrete for transportation projects.

Beneficiation of ammoniated fly ash

Boral has a chemical treatment technology that was developed to address moderate levels (<200 mg/kg) of ammonia in ash. The chemical treatment process, known as Ammonia Slip Mitigation (ASM), has been deployed at two power plants 1) the eastern bituminous fired units (4@ 253 MW total nameplate capacity) of Rochester Gas & Electric Russell Station – in this plant, ASM was used to treat an average of 3 truck-loads of ash per day with a total annual marketable ash production of about 10,000 tons; and 2) The East Lake station in Ohio - ASM was deployed to treat fly ash generated from a 600 MW unit burning a 50/50 blend of powder River Basin and Eastern Bituminous Coals. These plants used ASM to lower the ammonia in ash levels from up to 150 ppm to less than 50 ppm. Ammonia concentrations over 150 ppm were diverted to disposal. Higher levels of ammonia were also accompanied by wide variability, an issue that could not be solved by ASM.

The ASM technology requires robust quality control efforts to frequently test the ammonia in ash level to assure adequate treatment. Heightened quality control efforts were relatively simple to deploy at the above referenced small plants with low ash load-out rates.

ASM consists of adding a strong oxidizer, calcium hypochlorite, in powder form to the ash during load-out from the silo into a truck. The reagent is used to neutralize (oxidize) the ammonia once the ash gets wet in a concrete mixer. This approach works well with consistent and moderate ammonia levels. Higher ammonia levels and associated high reagent additions would lead to high levels of chlorides in concrete which is limited by many specifications. The ASM technology has not been demonstrated to deal with ammoniated ash at large power plant units requiring potentially complex quality control program.

Another commercially proven approach was developed by STI. It consists of wetting the ash and adding $\text{Ca}(\text{OH})_2$ to rapidly raise the pH to strip the ammonia then dry the ash. This approach has been deployed for low CaO eastern bituminous derived ash at a powerplant in Tampa. However, this chemical stripping of ammonia is not feasible for Coal Creek ash since it would increase the ash CaO content limiting its use in the market. It would require about 10% of lime by weight of ash to raise the pH to 12 for effective stripping. The 10% lime addition will drive the CaO content of the Coal Creek above 20%, making it not suitable for use in DOT specified projects to enhance durability of concrete.

Inconsistent and high levels of ammonia in ash from SNCR units can be thermally removed from the ash to maintain an effectively safe program for the beneficial use of ash in concrete. The state-of-the art thermal removal of ammonia from ash has not been commercially demonstrated. It requires a

significant capital investment for the thermal reactor, cooler, bag house and other ancillary equipment. Energy from the boiler or natural gas will be needed to raise the ash temperature for effective stripping of ammonia. The operating temperature will depend the ammonium salt species found in the ash. Temperatures ranging from 800 to 1400 °F have been cited as effective to remove ammonia from fly ash. Pilot scale testing will be required to confirm ammonia stripping temperature and retention time. The stripped ammonia can be returned to the boiler or scrubbed. Balance of plant issues much also be evaluated.

The costs to deploy the Ammonia Slip Mitigation technology at GRE Coal Creek Station was developed by Golder Associates in 2011 and updated in March 2019. The estimates were based on their review of the East Lake installation scaled up for deployment at the Coal Creek Station. The 2019 updates adequately cover the costs of ASM system installations and ancillary equipment such as a new truck load out silo dedicated for the ASM system and installing a second ASM system at the existing rail loadout silo. The ASM system at Coal Creek would be used to treat ash containing less than 150 mg/kg. Fly ash containing more than 150 mg/kg would be diverted to disposal via existing silos. The Golder 2019 updated study also includes the operating and maintenance costs associated with the use of the ASM technology to treat the ash.

It's very difficult to estimate the annual quantity of fly ash that would contain less than 150 mg/kg of ammonia and be suitable for treatment using ASM. This is due to the inherent site-specific performance capabilities of SNCR and variabilities expected by load cycling.

RE: Coal Creek Station Unit 2 NOx Emissions

Dear Mr. O'Clair:

We understand that you have been working with the U.S. Environmental Protection Agency ("EPA") to finalize the phase I regional haze state implementation plan ("SIP") for North Dakota. In connection with these efforts, you asked Great River Energy to discuss the NOx emission rates at Coal Creek Station, Unit 2 ("CCS2"), particularly the relatively lower NOx emission rates that CCS2 has achieved in the last 12-24 months. This letter responds to that request.

In its amended SIP, the North Dakota Department of Health ("NDDH") proposed a best available retrofit technology ("BART") limit of 0.17 lbs/mmBtu on a 30-day rolling average for NOx at CCS2. This limit was based on Great River Energy's use of our DryFining™ process for the coal and the installation of LNC3+ low NOx burners on CCS2. Great River Energy is pleased with the performance of CCS2 following the application of these technologies. These technologies allowed us to appreciably reduce our NOx emission rate.

Great River Energy continues to believe that NDDH's proposed BART limit is appropriate for CCS2 and hopes that EPA will concur with NDDH's determination. Based on our experience with these technologies and expectations of future operation, we are concerned that NOx emission rates will continue to have high variability and increase in the future.

There are two primary factors that affect the NOx emission rate at CCS2: the sodium content of the coal and the load variability of the boiler. In recent months, the NOx emission rate has benefitted from higher sodium coal and relatively steady-state generation. As discussed in detail below, Great River Energy cannot depend on the continuation of these trends because we have little control over coal sodium content or load variability. Thus, the proposed NOx emission rate, 0.17 lbs/mmBtu over 30 days, remains appropriate for CCS2.

Lignite Sodium Content

Lignite sodium content is a key variable that affects boiler operation and, as a result, NO_x performance. CCS2 was designed for the use of local lignite coal. The design anticipated a certain amount of slagging on the boiler walls which affects the rate of heat absorption by the boiler walls in the area of the main fireball. The quantity of sodium in the coal has a pronounced impact on the amount of slagging: as sodium levels drop, less slagging occurs. When CCS2 burns low-sodium coal and less slagging occurs, there is much greater heat absorption in the lower zone of the boiler and less heat reaches the upper reheat and superheat zones of the boiler. This lowers unit efficiency and raises the heat rate. As a result, CCS2 must burn more coal to produce the same amount of electricity.

Great River Energy has little ability to counter the loss of efficiency caused by the combustion of lower sodium coal. First, Great River Energy cannot dictate different coal specifications because CCS2 is a mine-mouth facility and designed to burn the coal from that mine. The mine's ability to blend coal for various constituents is limited because it typically operates only one or two pits. While the sodium content varies across the seam, it is logistically impractical for the mine to stockpile coal from the same mine to achieve a consistently higher sodium content. Second, because CCS2 is designed to maximize efficiency, the burners automatically adjust in response to an imbalance in the heat distribution. Low temperatures in the super heat section of the boiler automatically cause the burners to tilt upwards to move more heat to the upper sections of the boiler. When this happens, the fireball is extended upwards within the boiler, changing the fuel-air mixture in that section of the boiler and increasing NO_x emissions. The boiler operators have little ability to limit these automatic adjustments. Efforts to override the burner tilt controls adversely affect unit efficiency and emissions of NO_x and other pollutants.

Figure 1, attached, demonstrates the impact of sodium on the NO_x emission rate at CCS2. Figure 1 shows the sodium content of coal and the NO_x emissions over a four-year period (2014-2017). The green line shows short-term sodium concentration; the blue line shows the long-term average sodium concentration; and the red line reflects the 30-day rolling average NO_x emission rate. When sodium levels were low, particularly in the 2014-2015 time frame, the NO_x emission rate was significantly higher, with several periods exceeding 0.17 lbs/mmBtu. As sodium levels increased starting in early 2016, the NO_x emission rate began trending lower.

Even during periods when the average sodium levels were relatively high – above 3 percent – Great River Energy still observed significant short-term NO_x variability, including several very high NO_x spikes. This is because even short-term sodium variability impacts NO_x emissions; even a one- or two-week pocket of low-sodium coal will drive up the NO_x emission rate.

Load Variability

Load variability also is a key factor that affects NO_x rates at CCS2. CCS2 was designed as a baseload generating unit, operating in a steady-state, high-capacity mode. At a constant load, it is easier to manage and minimize NO_x emissions. NO_x emissions increase when CCS2 is required to ramp up and down based on demands from our independent system operator, Midcontinent Independent System Operator ("MISO").

When Great River Energy proposed the CCS2 BART limit to NDDH, we did not envision CCS2 becoming a load-following unit. However, the last decade has seen dramatic increases in renewable energy penetration in the MISO region. As a result, MISO has been increasingly requiring CCS2 to "chase load"

over extended periods. As an example, between 2012 and 2014 CCS2 operated in "low load" mode (30 - 40 percent of maximum capacity) less than 10 hours per year. In 2016, that increased to 249 hours. The amount of planned and announced wind development in the MISO region promises to increase this trend.

The impact of load shifts on NOx emission rates, particularly low-load and ramping operation, is demonstrated in Figures 2 and 3, also attached. Figure 2 depicts the direct, inverse relationship between load levels and NOx emission rates over a five-day period when sodium levels in the coal were low (<2 percent). The red line shows the hourly load levels; the dark blue line shows the hourly NOx emission rate; and the light blue line shows the 24-hr rolling average NOx rate over the period. The NOx emission rates (hourly and 24-hr average) were consistently above 0.2 lbs/mmBtu over this five-day period due to the combination of low sodium and high load variability.

Figure 3 shows a different period when the sodium levels were above 3 percent, where we would have expected NOx rates to be correspondingly lower. Instead, CCS2 experienced higher than expected NOx emission rates because of the highly variable load demands, with the 24-hr average rate hovering at or above 0.17 lbs/mmBtu. It takes only a few periods like that reflected in Figure 3 to drive the 30-day rolling average NOx emission rate above 0.17 lbs/mmBtu.

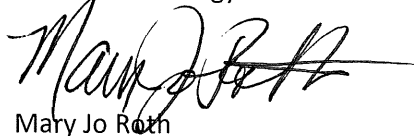

Conclusion

CCS2 has achieved significant improvement in its NOx performance as a result of Great River Energy's DryFining™ process and the installation of LNC3+ burners. As Great River Energy works to ensure that we can achieve the proposed BART emission rate of 0.17 lbs/mmBtu, two variables – sodium content and load variability – will continue to be impediments and these variables are largely out of Great River Energy's control. Accordingly, Great River Energy hopes that EPA will concur with NDDH's determination that 0.17 lbs/mmBtu is an appropriate BART limit.

Please contact me at (763-445-5212) if you have any questions or wish to discuss any of the above.

Sincerely,

Great River Energy

Mary Jo Roth

Mr. James L. Semerad
Director, Division of Air Quality
North Dakota Department of Environmental Quality
918 E. Divide Avenue, 2nd Floor
Bismarck, North Dakota 58501-1947

Dear Mr. Semerad:

On March 21, 2019, the North Dakota Department of Environmental Quality (NDDEQ) shared the *Protocol for BART-Related Visibility Impairment Modeling Analysis, Great River Energy Coal Creek Station (March 2019)* with the Environmental Protection Agency (EPA) by email for our review. The EPA provided comments on the protocol to NDDEQ in our letter dated April 8, 2019. Subsequently, on July 8, 2019, NDDEQ provided a revised protocol that addressed the concerns raised by the EPA, with the exception of the modeled scenarios and several other items detailed in the email sent by Aaron Worstell, of my staff, on July 10, 2019. On July 26, 2019, after further coordination between Great River Energy, NDDEQ, and the EPA, a final protocol was submitted to the EPA addressing these remaining concerns. With this letter, the EPA is approving the modeling methods and assumptions contained in the final modeling protocol.

In our comments of April 8, 2019, the EPA stated that the protocol did not provide enough detail to explain how the emission units and control scenarios will be combined in POSTUTIL and subsequently in CALPUFF (see item 31). The final protocol has largely addressed this concern. To ensure that the concern is fully addressed during implementation, we request that NDDEQ provide us with sample POSTUTIL input files prior to running the module to ensure that the configuration aligns with our preferred approach.

We understand that the protocol is intended to support a future State Implementation Plan (SIP) revision addressing Best Available Retrofit Technology requirements for nitrogen oxides at Coal Creek Station. Please note that we will only reach a final conclusion regarding the adequacy of the SIP revision when we act on the SIP submittal through notice and comment rulemaking.

We appreciate the opportunity to provide input on the modeling protocol. If you have any additional questions, please contact Aaron Worstell, of my staff, at 303-312-6073 or worstell.aaron@epa.gov.

Sincerely,

8/7/2019

 Carl Daly

EXTERNAL

Morning Greg,

Attached you will find EPA's approval of the modeling protocol for the revised NOx BART analysis.

GRE CCS can proceed forward with the modeling as outlined. Let me know if you have any questions or comments.

Thanks,

David Stroh
Environmental Engineer

EPA Control Cost Manual SCR and SNCR Spreadsheets for Units 1 and 2

Data Inputs

Coal Creek SCR Cost Estimate for 2019 BART - 0.06 lb NOx/MMBtu EPA calculations for flue gas flow and catalyst volume. Use anhydrous ammonia Meth 2 Cat Rep Cost EPA Default Cat Cost.

Enter the following data for your combustion unit:

Is the combustion unit a utility or industrial boiler?

Utility ▼

What type of fuel does the unit burn?

Coal ▼

Is the SCR for a new boiler or retrofit of an existing boiler?

Retrofit ▼

Please enter a retrofit factor between 0.8 and 1.5 based on the level of difficulty. Enter 1 for projects of average retrofit difficulty.

1

Complete all of the highlighted data fields:

What is the MW rating at full load capacity (Bmw)?

605 MW

What is the higher heating value (HHV) of the fuel?

6,685 Btu/lb

What is the estimated actual annual MWhs output?

4,610,826 MWhs

87% capacity factor

Enter the net plant heat input rate (NPHR)

10 MMBtu/MW

If the NPHR is not known, use the default NPHR value:

Fuel Type	Default NPHR
Coal	10 MMBtu/MW
Fuel Oil	11 MMBtu/MW
Natural Gas	8.2 MMBtu/MW

Plant Elevation

1980 Feet above sea level

Provide the following information for coal-fired boilers:

Type of coal burned:

Lignite ▼

Enter the sulfur content (%S) =

0.82 percent by weight

CCS data sulfur content

For units burning coal blends:

Note: The table below is pre-populated with default values for HHV and %S. Please enter the actual values for these parameters in the table below. If the actual value for any parameter is not known, you may use the default values provided.

Coal Type	Fraction in Coal Blend	%S	HHV (Btu/lb)
Bituminous	0	1.84	11,841
Sub-Bituminous	0	0.41	8,826
Lignite	0	0.82	6,685

Please click the calculate button to calculate weighted average values based on the data in the table above.

For coal-fired boilers, you may use either Method 1 or Method 2 to calculate the catalyst replacement cost. The equations for both methods are shown on rows 85 and 86 on the **Cost Estimate** tab. Please select your preferred method:

- ☐ Method 1
☒ Method 2
☐ Not applicable

Enter the following design parameters for the proposed SCR:

Number of days the SCR operates (t_{SCR})

365 days

Number of days the boiler operates (t_{plant})

365 days

Inlet NO_x Emissions ($NO_{x,in}$) to SCR

0.13 lb/MMBtu

Outlet NO_x Emissions ($NO_{x,out}$) from SCR

0.06 lb/MMBtu

Stoichiometric Ratio Factor (SRF)

1.050

*The SRF value of 1.05 is a default value. User should enter actual value, if known.

Number of SCR reactor chambers (n_{scr})

1

Number of catalyst layers (R_{layer})

3 Replace all catalyst every 3 years

Number of empty catalyst layers (R_{empty})

1

Ammonia Slip (Slip) provided by vendor

2 ppm

Volume of the catalyst layers ($Vol_{catalyst}$)
(Enter "UNK" if value is not known)

UNK Cubic feet (confidential)

Flue gas flow rate ($Q_{fluegas}$)

(Enter "UNK" if value is not known)

UNK acfm

Estimated operating life of the catalyst ($H_{catalyst}$)

24,000 hours

Estimated SCR equipment life

30 Years*

* For utility boilers, the typical equipment life of an SCR is at least 30 years.

Gas temperature at the SCR inlet (T)

650 °F

Base case fuel gas volumetric flow rate factor (Q_{fuel})

547 ft³/min-MMBtu/hour

Concentration of reagent as stored (C_{stored})

29 percent*

Density of reagent as stored (ρ_{stored})

56 lb/cubic feet*

Number of days reagent is stored ($t_{storage}$)

14 days

*The reagent concentration of 29% and density of 56 lbs/cft are default values for ammonia reagent. User should enter actual values for reagent, if different from the default values provided.

Densities of typical SCR reagents:

50% urea solution	71 lbs/ft ³
29.4% aqueous NH ₃	56 lbs/ft ³

Select the reagent used

Ammonia

Enter the cost data for the proposed SCR:

Desired dollar-year

2018

CEPCI for 2018

615.3 Enter the CEPCI value for 2018

541.7

2016 CEPCI

CEPCI = Chemical Engineering Plant Cost Index

Annual Interest Rate (i)

5.25 Percent

Reagent ($Cost_{reag}$)

0.293 \$/gallon for 29% ammonia*

* \$0.293/gallon is a default value for 29% ammonia. User should enter actual value, if known.

Electricity ($Cost_{elect}$)

0.0361 \$/kWh

* \$0.0361/kWh is a default value for electricity cost. User should enter actual value, if known.

Catalyst cost ($CC_{replace}$)

227.00

\$/cubic foot (includes removal and disposal/regeneration of existing catalyst and installation of new catalyst)

* \$227/cf is a default value for the catalyst cost based on 2016 prices. User should enter actual value, if known.

Operator Labor Rate

60.00 \$/hour (including benefits)*

* \$60/hour is a default value for the operator labor rate. User should enter actual value, if known.

Operator Hours/Day

4.00 hours/day*

* 4 hours/day is a default value for the operator labor. User should enter actual value, if known.

Note: The use of CEPCI in this spreadsheet is not an endorsement of the index, but is there merely to allow for availability of a well-known cost index to spreadsheet users. Use of other well-known cost indexes (e.g., M&S) is acceptable.

Maintenance and Administrative Charges Cost Factors:

Maintenance Cost Factor (MCF) =	0.005
Administrative Charges Factor (ACF) =	0.03

SCR Design Parameters

Coal Creek SCR Cost Estimate for 2019 BART - 0.06 lb NO_x/MMBtu EPA calculations for flue gas flow and catalyst volume. Use anhydrous ammonia Meth 2 Cat Rep Cost EPA Default Cat Cost.

The following design parameters for the SCR were calculated based on the values entered on the *Data Inputs* tab. These values were used to prepare the costs shown on the *Cost Estimate* tab.

Parameter	Equation	Calculated Value	Units
Maximum Annual Heat Input Rate (Q_B) =	$Bmw \times NPHR =$	6,050	MMBtu/hour
Maximum Annual MW Output (Bmw) =	$Bmw \times 8760 =$	5,299,800	MWhts
Estimated Actual Annual MWhts Output (Boutput) =		4,610,826	MWhts
Heat Rate Factor (HRF) =	$NPHR/10 =$	1.00	
Total System Capacity Factor (CF_{total}) =	$(Boutput/Bmw) \times (tscr/tplant) =$	0.870	fraction
Total operating time for the SCR (t_{op}) =	$CF_{total} \times 8760 =$	7621	hours
NO _x Removal Efficiency (EF) =	$(NO_{x,in} - NO_{x,out})/NO_{x,in} =$	53.8	percent
NO _x removed per hour =	$NO_{x,in} \times EF \times Q_B =$	423.50	lb/hour
Total NO _x removed per year =	$(NO_{x,in} \times EF \times Q_B \times t_{op})/2000 =$	1,613.79	tons/year
NO _x removal factor (NRF) =	$EF/80 =$	0.67	
Volumetric flue gas flow rate ($q_{flue\ gas}$) =	$Q_{fuel} \times QB \times (460 + T)/(460 + 700)n_{scr} =$	3,166,706	acfm
Space velocity (V_{space}) =	$q_{flue\ gas}/Vol_{catalyst} =$	181.21	/hour
Residence Time	$1/V_{space}$	0.01	hour
Coal Factor (CoalF) =	1 for oil and natural gas; 1 for bituminous; 1.05 for sub-bituminous; 1.07 for lignite (weighted average is used for coal blends)	1.07	
SO ₂ Emission rate =	$(\%S/100) \times (64/32) \times 1 \times 10^6 / HHV =$	< 3	lbs/MMBtu
Elevation Factor (ELEVf) =	$14.7\ psia/P =$	1.07	
Atmospheric pressure at sea level (P) =	$2116 \times [(59 - (0.00356 \times h) + 459.7)/518.6]^{5.256} \times (1/144)^* =$	13.7	psia
Retrofit Factor (RF)	Retrofit to existing boiler	1.00	

* Equation is from the National Aeronautics and Space Administration (NASA), Earth Atmosphere Model. Available at <https://spaceflightsystems.grc.nasa.gov/education/rocket/atmos.html>.

Catalyst Data:

Parameter	Equation	Calculated Value	Units
Future worth factor (FWF) =	$(\text{interest rate}) / (1 / ((1 + \text{interest rate})^Y - 1))$, where $Y = H_{\text{catalyst}} / (t_{\text{SCR}} \times 24 \text{ hours})$ rounded to the nearest integer	0.3164	Fraction
Catalyst volume (Vol_{catalyst}) =	$2.81 \times Q_G \times EF_{\text{adj}} \times Slip_{\text{adj}} \times NOx_{\text{adj}} \times S_{\text{adj}} \times (T_{\text{adj}} / N_{\text{scr}})$	17,475.38	Cubic feet
Cross sectional area of the catalyst (A_{catalyst}) =	$Q_{\text{flue gas}} / (16 \text{ ft/sec} \times 60 \text{ sec/min})$	3,299	ft ²
Height of each catalyst layer (H_{layer}) =	$(Vol_{\text{catalyst}} / (R_{\text{layer}} \times A_{\text{catalyst}})) + 1$ (rounded to next highest integer)	3	feet

SCR Reactor Data:

Parameter	Equation	Calculated Value	Units
Cross sectional area of the reactor (A_{SCR}) =	$1.15 \times A_{\text{catalyst}}$	3,793	ft ²
Reactor length and width dimensions for a square reactor =	$(A_{\text{SCR}})^{0.5}$	61.6	feet
Reactor height =	$(R_{\text{layer}} + R_{\text{empty}}) \times (7 \text{ ft} + h_{\text{layer}}) + 9 \text{ ft}$	48	feet

Reagent Data:

Type of reagent used	Ammonia	Molecular Weight of Reagent (MW) =	17.03 g/mole
		Density =	56 lb/ft ³

Parameter	Equation	Calculated Value	Units
Reagent consumption rate (m_{reagent}) =	$(NOx_{\text{in}} \times Q_G \times EF \times SRF \times MW_R) / MW_{NOx} =$	165	lb/hour
Reagent Usage Rate (m_{sol}) =	$m_{\text{reagent}} / C_{\text{sol}} =$	568	lb/hour
	$(m_{\text{sol}} \times 7.4805) / \text{Reagent Density}$	76	gal/hour
Estimated tank volume for reagent storage =	$(m_{\text{sol}} \times 7.4805 \times t_{\text{storage}} \times 24) / \text{Reagent Density} =$	25,500	gallons (storage needed to store a 14 day reagent supply rounded to the ne

Capital Recovery Factor:

Parameter	Equation	Calculated Value
Capital Recovery Factor (CRF) =	$i (1 + i)^n / ((1 + i)^n - 1) =$ Where n = Equipment Life and i = Interest Rate	0.0669

Other parameters	Equation	Calculated Value	Units
Electricity Usage:			
Electricity Consumption (P) =	$A \times 1,000 \times 0.0056 \times (\text{CoalF} \times \text{HRF})^{0.43} =$ where A = Bmw for utility boilers	3488.02	kW

Cost Estimate

Coal Creek SCR Cost Estimate for 2019 BART - 0.06 lb NOx/MMBtu EPA calculations for flue gas flow and catalyst volume. Use anhydrous ammonia Meth 2 Cat Rep Cost EPA Default Cat Cost.

Total Capital Investment (TCI)

TCI for Coal-Fired Boilers

For Coal-Fired Boilers:

$$TCI = 1.3 \times (SCR_{cost} + RPC + APHC + BPC)$$

Capital costs for the SCR (SCR_{cost})** =	\$134,743,323	in 2018 dollars
Reagent Preparation Cost (RPC) =	\$2,906,167	in 2018 dollars
Air Pre-Heater Costs (APHC)* =	\$0	in 2018 dollars
Balance of Plant Costs (BPC) =	\$9,781,799	in 2018 dollars
Total Capital Investment (TCI) =	\$191,660,675	in 2018 dollars

* Not applicable - This factor applies only to coal-fired boilers that burn bituminous coal and emits equal to or greater than 3lb/MMBtu of sulfur dioxide.

** Cost estimate for SCR Reactor from Version 10 spreadsheet at 0.04 lb NOx/MMBtu was \$141.8M. Size and cost of reactor is not reduced at performance rating of 0.06 lb NOx/MMBtu. A 0.06 lb NOx/MMBtu performance rating reflects an optimistic estimate of the 3-year average performance of the SCR catalyst in this service based actual performance of the best performing power plant of two plants firing Texas Lignite. Actual performance could be lower based on the higher sodium content of North Dakota lignite versus Texas lignite

SCR Capital Costs (SCR_{cost})

For Coal-Fired Utility Boilers >25 MW:

$$SCR_{cost} = 310,000 \times (NRF)^{0.2} \times (B_{MW} \times HRF \times CoalF)^{0.92} \times ELEVF \times RF$$

For Coal-Fired Industrial Boilers >250 MMBtu/hour:

$$SCR_{cost} = 310,000 \times (NRF)^{0.2} \times (0.1 \times Q_B \times CoalF)^{0.92} \times ELEVF \times RF$$

SCR Capital Costs (SCR_{cost}) =	\$134,743,323 in 2018 dollars
--------------------------------------	-------------------------------

Reagent Preparation Costs (RPC)

For Coal-Fired Utility Boilers >25 MW:

$$RPC = 564,000 \times (NO_{x,in} \times B_{MW} \times NPHR \times EF)^{0.25} \times RF$$

For Coal-Fired Industrial Boilers >250 MMBtu/hour:

$$RPC = 564,000 \times (NO_{x,in} \times Q_B \times EF)^{0.25} \times RF$$

Reagent Preparation Costs (RPC) =	\$2,906,167 in 2018 dollars
-----------------------------------	-----------------------------

Air Pre-Heater Costs (APHC)*

For Coal-Fired Utility Boilers >25MW:

$$APHC = 69,000 \times (B_{MW} \times HRF \times CoalF)^{0.78} \times AHF \times RF$$

For Coal-Fired Industrial Boilers >250 MMBtu/hour:

$$APHC = 69,000 \times (0.1 \times Q_B \times CoalF)^{0.78} \times AHF \times RF$$

Air Pre-Heater Costs (APH_{cost}) =	\$0 in 2018 dollars
---	---------------------

* Not applicable - This factor applies only to coal-fired boilers that burn bituminous coal and emit equal to or greater than 3lb/MMBtu of sulfur dioxide.

Balance of Plant Costs (BPC)

For Coal-Fired Utility Boilers >25MW:

$$BPC = 529,000 \times (B_{MW} \times HRF \times CoalF)^{0.42} \times ELEVF \times RF$$

For Coal-Fired Industrial Boilers >250 MMBtu/hour:

$$BPC = 529,000 \times (0.1 \times Q_B \times CoalF)^{0.42} \times ELEVF \times RF$$

Balance of Plant Costs (BOP_{cost}) =	\$9,781,799 in 2018 dollars
---	-----------------------------

Annual Costs

Total Annual Cost (TAC)

$$\text{TAC} = \text{Direct Annual Costs} + \text{Indirect Annual Costs}$$

Direct Annual Costs (DAC) =	\$3,868,611 in 2018 dollars
Indirect Annual Costs (IDAC) =	\$12,836,227 in 2018 dollars
Total annual costs (TAC) = DAC + IDAC	\$16,704,838 in 2018 dollars

Direct Annual Costs (DAC)

$$\text{DAC} = (\text{Annual Maintenance Cost}) + (\text{Annual Reagent Cost}) + (\text{Annual Electricity Cost}) + (\text{Annual Catalyst Cost})$$

Annual Maintenance Cost =	$0.005 \times \text{TCI} =$	\$958,303 in 2018 dollars
Annual Reagent Cost =	$m_{\text{sol}} \times \text{Cost}_{\text{reag}} \times t_{\text{op}} =$	\$169,294 in 2018 dollars
Annual Electricity Cost =	$P \times \text{Cost}_{\text{elect}} \times t_{\text{op}} =$	\$959,641 in 2018 dollars
Annual Catalyst Replacement Cost =		\$1,781,373 in 2018 dollars
For coal-fired boilers, the following methods may be used to calculate the catalyst replacement cost.		
Method 1 (for all fuel types):	$n_{\text{scr}} \times \text{Vol}_{\text{cat}} \times (\text{CC}_{\text{replace}}/\text{R}_{\text{layer}}) \times \text{FWF}$	* Calculation Method 2 selected.
Method 2 (for coal-fired utility boilers):	$B_{\text{MW}} \times 0.4 \times (\text{CoalF})^{2.9} \times (\text{NRF})^{0.71} \times (\text{CC}_{\text{replace}}) \times 35.3$	
Direct Annual Cost =		\$3,868,611 in 2018 dollars

Indirect Annual Cost (IDAC)

$$\text{IDAC} = \text{Administrative Charges} + \text{Capital Recovery Costs}$$

Administrative Charges (AC) =	$0.03 \times (\text{Operator Cost} + 0.4 \times \text{Annual Maintenance Cost}) =$	\$14,128 in 2018 dollars
Capital Recovery Costs (CR)=	$\text{CRF} \times \text{TCI} =$	\$12,822,099 in 2018 dollars
Indirect Annual Cost (IDAC) =	$\text{AC} + \text{CR} =$	\$12,836,227 in 2018 dollars

Cost Effectiveness

$$\text{Cost Effectiveness} = \text{Total Annual Cost} / \text{NOx Removed/year}$$

Total Annual Cost (TAC) =	\$16,704,838 per year in 2018 dollars
NOx Removed =	1,614 tons/year
Cost Effectiveness =	\$10,351 per ton of NOx removed in 2018 dollars

Data Inputs

Coal Creek SCR Cost Estimate for 2019 BART - 0.08 lb NOx/MMBtu EPA calculations for flue gas flow and catalyst volume. Use anhydrous ammonia Meth 2 Cat Rep Cost EPA Default Cat Cost.

Enter the following data for your combustion unit:

Is the combustion unit a utility or industrial boiler?

Utility ▼

What type of fuel does the unit burn?

Coal ▼

Is the SCR for a new boiler or retrofit of an existing boiler?

Retrofit ▼

Please enter a retrofit factor between 0.8 and 1.5 based on the level of difficulty. Enter 1 for projects of average retrofit difficulty.

1

Complete all of the highlighted data fields:

EPA default value used

Site specific data entered

What is the MW rating at full load capacity (Bmw)?

605 MW

What is the higher heating value (HHV) of the fuel?

6,685 Btu/lb

*HHV value of 6685 Btu/lb is a default value. See below for data source. Enter actual HHV for fuel burned, if known.

What is the estimated actual annual MWhs output?

4,610,826 MWhs

87% capacity factor

Enter the net plant heat input rate (NPHR)

10 MMBtu/MW

If the NPHR is not known, use the default NPHR value:

Fuel Type	Default NPHR
Coal	10 MMBtu/MW
Fuel Oil	11 MMBtu/MW
Natural Gas	8.2 MMBtu/MW

Plant Elevation

1980

Feet above sea level

Provide the following information for coal-fired boilers:

Type of coal burned:

Lignite ▼

Enter the sulfur content (%S) =

0.82 percent by weight

CCS data sulfur content and HHV

For units burning coal blends:

Note: The table below is pre-populated with default values for HHV and %S. Please enter the actual values for these parameters in the table below. If the actual value for any parameter is not known, you may use the default values provided.

Coal Type	Fraction in Coal Blend	%S	HHV (Btu/lb)
Bituminous	0	1.84	11,841
Sub-Bituminous	0	0.41	8,826
Lignite	0	0.82	6,685

Please click the calculate button to calculate weighted average values based on the data in the table above.

For coal-fired boilers, you may use either Method 1 or Method 2 to calculate the catalyst replacement cost. The equations for both methods are shown on rows 85 and 86 on the **Cost Estimate** tab. Please select your preferred method:

- ☐ Method 1
☒ Method 2
☐ Not applicable

Enter the following design parameters for the proposed SCR:

Number of days the SCR operates (t_{SCR})

365 days

Number of days the boiler operates (t_{plant})

365 days

Inlet NO_x Emissions ($NO_{x,in}$) to SCR

0.13 lb/MMBtu

Outlet NO_x Emissions ($NO_{x,out}$) from SCR

0.08 lb/MMBtu

Stoichiometric Ratio Factor (SRF)

1.050

*The SRF value of 1.05 is a default value. User should enter actual value, if known.

Number of SCR reactor chambers (n_{scr})

1

Number of catalyst layers (R_{layer})

3 Replace all catalyst every 3 years

Number of empty catalyst layers (R_{empty})

1

Ammonia Slip (Slip) provided by vendor

2 ppm

Volume of the catalyst layers ($Vol_{catalyst}$)
(Enter "UNK" if value is not known)

UNK Cubic feet (confidential)

Flue gas flow rate ($Q_{fluegas}$)

(Enter "UNK" if value is not known)

UNK acfm

Estimated operating life of the catalyst ($H_{catalyst}$)

24,000 hours

Estimated SCR equipment life

30 Years*

* For utility boilers, the typical equipment life of an SCR is at least 30 years.

Gas temperature at the SCR inlet (T)

650 °F

Base case fuel gas volumetric flow rate factor (Q_{fuel})

547 ft³/min-MMBtu/hour

Concentration of reagent as stored (C_{stored})

29 percent*

Density of reagent as stored (ρ_{stored})

56 lb/cubic feet*

Number of days reagent is stored ($t_{storage}$)

14 days

*The reagent concentration of 29% and density of 56 lbs/cft are default values for ammonia reagent. User should enter actual values for reagent, if different from the default values provided.

Densities of typical SCR reagents:

50% urea solution	71 lbs/ft ³
29.4% aqueous NH ₃	56 lbs/ft ³

Select the reagent used

SCR Design Parameters

Coal Creek SCR Cost Estimate for 2019 BART - 0.08 lb NO_x/MMBtu EPA calculations for flue gas flow and catalyst volume. Use anhydrous ammonia Meth 2 Cat Rep Cost EPA Default Cat Cost.

The following design parameters for the SCR were calculated based on the values entered on the *Data Inputs* tab. These values were used to prepare the costs shown on the *Cost Estimate* tab.

Parameter	Equation	Calculated Value	Units
Maximum Annual Heat Input Rate (Q_B) =	$Bmw \times NPHR =$	6,050	MMBtu/hour
Maximum Annual MW Output (Bmw) =	$Bmw \times 8760 =$	5,299,800	MWhrs
Estimated Actual Annual MWs Output (Boutput) =		4,610,826	MWhrs
Heat Rate Factor (HRF) =	$NPHR/10 =$	1.00	
Total System Capacity Factor (CF_{total}) =	$(Boutput/Bmw) \times (tscr/tplant) =$	0.870	fraction
Total operating time for the SCR (t_{op}) =	$CF_{total} \times 8760 =$	7621	hours
NO _x Removal Efficiency (EF) =	$(NO_{x_{in}} - NO_{x_{out}})/NO_{x_{in}} =$	38.5	percent
NO _x removed per hour =	$NO_{x_{in}} \times EF \times Q_B =$	302.50	lb/hour
Total NO _x removed per year =	$(NO_{x_{in}} \times EF \times Q_B \times t_{op})/2000 =$	1,152.71	tons/year
NO _x removal factor (NRF) =	$EF/80 =$	0.48	
Volumetric flue gas flow rate ($q_{flue\ gas}$) =	$Q_{fuel} \times QB \times (460 + T)/(460 + 700)n_{scr} =$	3,166,706	acfm
Space velocity (V_{space}) =	$q_{flue\ gas}/Vol_{catalyst} =$	223.72	/hour
Residence Time	$1/V_{space}$	0.00	hour
Coal Factor (CoalF) =	1 for oil and natural gas; 1 for bituminous; 1.05 for sub-bituminous; 1.07 for lignite (weighted average is used for coal blends)	1.07	
SO ₂ Emission rate =	$(\%S/100) \times (64/32) \times 1 \times 10^6 / HHV =$	< 3	lbs/MMBtu
Elevation Factor (ELEVf) =	$14.7\ psia/P =$	1.07	
Atmospheric pressure at sea level (P) =	$2116 \times [(59 - (0.00356 \times h) + 459.7)/518.6]^{5.256} \times (1/144) * =$	13.7	psia
Retrofit Factor (RF)	Retrofit to existing boiler	1.00	

* Equation is from the National Aeronautics and Space Administration (NASA), Earth Atmosphere Model. Available at <https://spaceflightsystems.grc.nasa.gov/education/rocket/atmos.html>.

Catalyst Data:

Parameter	Equation	Calculated Value	Units
Future worth factor (FWF) =	$(\text{interest rate}) / (1 / ((1 + \text{interest rate})^Y - 1))$, where $Y = H_{\text{catalyst}} / (t_{\text{SCR}} \times 24 \text{ hours})$ rounded to the nearest integer	0.3164	Fraction
Catalyst volume (Vol_{catalyst}) =	$2.81 \times Q_G \times EF_{\text{adj}} \times Slip_{\text{adj}} \times NOx_{\text{adj}} \times S_{\text{adj}} \times (T_{\text{adj}} / N_{\text{scr}})$	14,154.71	Cubic feet
Cross sectional area of the catalyst (A_{catalyst}) =	$Q_{\text{flue gas}} / (16 \text{ ft/sec} \times 60 \text{ sec/min})$	3,299	ft ²
Height of each catalyst layer (H_{layer}) =	$(Vol_{\text{catalyst}} / (R_{\text{layer}} \times A_{\text{catalyst}})) + 1$ (rounded to next highest integer)	2	feet

SCR Reactor Data:

Parameter	Equation	Calculated Value	Units
Cross sectional area of the reactor (A_{SCR}) =	$1.15 \times A_{\text{catalyst}}$	3,793	ft ²
Reactor length and width dimensions for a square reactor =	$(A_{\text{SCR}})^{0.5}$	61.6	feet
Reactor height =	$(R_{\text{layer}} + R_{\text{empty}}) \times (7 \text{ ft} + h_{\text{layer}}) + 9 \text{ ft}$	47	feet

Reagent Data:

Other parameters	Equation	Calculated Value	Units
Electricity Usage:			
Electricity Consumption (P) =	$A \times 1,000 \times 0.0056 \times (\text{CoalF} \times \text{HRF})^{0.43} =$ where A = Bmw for utility boilers	3488.02	kW

Cost Estimate

Coal Creek SCR Cost Estimate for 2019 BART - 0.08 lb NOx/MMBtu EPA calculations for flue gas flow and catalyst volume. Use anhydrous ammonia Meth 2 Cat Rep Cost EPA Default Cat Cost.

Total Capital Investment (TCI)

TCI for Coal-Fired Boilers

For Coal-Fired Boilers:

$$TCI = 1.3 \times (SCR_{cost} + RPC + APHC + BPC)$$

Capital costs for the SCR (SCR_{cost}) =	\$125,974,211	in 2018 dollars
Reagent Preparation Cost (RPC) =	\$2,671,705	in 2018 dollars
Air Pre-Heater Costs (APHC)* =	\$0	in 2018 dollars
Balance of Plant Costs (BPC) =	\$9,781,799	in 2018 dollars
Total Capital Investment (TCI) =	\$179,956,029	in 2018 dollars

* Not applicable - This factor applies only to coal-fired boilers that burn bituminous coal and emits equal to or greater than 3lb/MMBtu of sulfur dioxide.

SCR Capital Costs (SCR_{cost})

For Coal-Fired Utility Boilers >25 MW:

$$SCR_{cost} = 310,000 \times (NRF)^{0.2} \times (B_{MW} \times HRF \times CoalF)^{0.92} \times ELEVF \times RF$$

For Coal-Fired Industrial Boilers >250 MMBtu/hour:

$$SCR_{cost} = 310,000 \times (NRF)^{0.2} \times (0.1 \times Q_b \times CoalF)^{0.92} \times ELEVF \times RF$$

SCR Capital Costs (SCR_{cost}) = \$125,974,211 in 2018 dollars

Reagent Preparation Costs (RPC)

For Coal-Fired Utility Boilers >25 MW:

$$RPC = 564,000 \times (NO_{x,in} \times B_{MW} \times NPHR \times EF)^{0.25} \times RF$$

For Coal-Fired Industrial Boilers >250 MMBtu/hour:

$$RPC = 564,000 \times (NO_{x,in} \times Q_b \times EF)^{0.25} \times RF$$

Reagent Preparation Costs (RPC) = \$2,671,705 in 2018 dollars

Air Pre-Heater Costs (APHC)*

For Coal-Fired Utility Boilers >25MW:

$$APHC = 69,000 \times (B_{MW} \times HRF \times CoalF)^{0.78} \times AHF \times RF$$

For Coal-Fired Industrial Boilers >250 MMBtu/hour:

$$APHC = 69,000 \times (0.1 \times Q_b \times CoalF)^{0.78} \times AHF \times RF$$

Air Pre-Heater Costs (APH_{cost}) = \$0 in 2018 dollars

* Not applicable - This factor applies only to coal-fired boilers that burn bituminous coal and emit equal to or greater than 3lb/MMBtu of sulfur dioxide.

Balance of Plant Costs (BPC)

For Coal-Fired Utility Boilers >25MW:

$$BPC = 529,000 \times (B_{MW} \times HRF \times CoalF)^{0.42} \times ELEVF \times RF$$

For Coal-Fired Industrial Boilers >250 MMBtu/hour:

$$BPC = 529,000 \times (0.1 \times Q_b \times CoalF)^{0.42} \times ELEVF \times RF$$

Balance of Plant Costs (BOP_{cost}) = \$9,781,799 in 2018 dollars

Annual Costs

Total Annual Cost (TAC)

$$\text{TAC} = \text{Direct Annual Costs} + \text{Indirect Annual Costs}$$

Direct Annual Costs (DAC) =	\$3,383,172 in 2018 dollars
Indirect Annual Costs (IDAC) =	\$12,052,484 in 2018 dollars
Total annual costs (TAC) = DAC + IDAC	\$15,435,656 in 2018 dollars

Direct Annual Costs (DAC)

$$\text{DAC} = (\text{Annual Maintenance Cost}) + (\text{Annual Reagent Cost}) + (\text{Annual Electricity Cost}) + (\text{Annual Catalyst Cost})$$

Annual Maintenance Cost =	$0.005 \times \text{TCI} =$	\$899,780 in 2018 dollars
Annual Reagent Cost =	$m_{\text{sol}} \times \text{Cost}_{\text{reag}} \times t_{\text{op}} =$	\$120,924 in 2018 dollars
Annual Electricity Cost =	$P \times \text{Cost}_{\text{elect}} \times t_{\text{op}} =$	\$959,641 in 2018 dollars
Annual Catalyst Replacement Cost =		\$1,402,826 in 2018 dollars
For coal-fired boilers, the following methods may be used to calculate the catalyst replacement cost.		
Method 1 (for all fuel types):	$n_{\text{scr}} \times \text{Vol}_{\text{cat}} \times (\text{CC}_{\text{replace}} / R_{\text{layer}}) \times \text{FWF}$	* Calculation Method 2 selected.
Method 2 (for coal-fired utility boilers):	$B_{\text{MW}} \times 0.4 \times (\text{CoalF})^{2.9} \times (\text{NRF})^{0.71} \times (\text{CC}_{\text{replace}}) \times 35.3$	
Direct Annual Cost =		\$3,383,172 in 2018 dollars

Indirect Annual Cost (IDAC)

$$\text{IDAC} = \text{Administrative Charges} + \text{Capital Recovery Costs}$$

Administrative Charges (AC) =	$0.03 \times (\text{Operator Cost} + 0.4 \times \text{Annual Maintenance Cost}) =$	\$13,425 in 2018 dollars
Capital Recovery Costs (CR)=	$\text{CRF} \times \text{TCI} =$	\$12,039,058 in 2018 dollars
Indirect Annual Cost (IDAC) =	$\text{AC} + \text{CR} =$	\$12,052,484 in 2018 dollars

Cost Effectiveness

$$\text{Cost Effectiveness} = \text{Total Annual Cost} / \text{NOx Removed/year}$$

Total Annual Cost (TAC) =	\$15,435,656 per year in 2018 dollars
NOx Removed =	1,153 tons/year
Cost Effectiveness =	\$13,391 per ton of NOx removed in 2018 dollars

SNCR Design Parameters

Coal Creek SNCR w MNL Cost Estimate for 2019 BART - 0.10 lb NO_x/MMBtu

The following design parameters for the SNCR were calculated based on the values entered on the *Data Inputs* tab. These values were used to prepare the costs shown on the *Cost Estimate* tab.

Parameter	Equation	Calculated Value	Units
Maximum Annual Heat Input Rate (Q _B) =	Bmw x NPHR =	6,050	MMBtu/hour
Maximum Annual MWh Output =	Bmw x 8760 =	5,299,800	MWh
Estimated Actual Annual MWh Output (Boutput) =		4,610,826	MWh
Heat Rate Factor (HRF) =	NPHR/10 =	1.00	
Total System Capacity Factor (CF _{total}) =	(Boutput/Bmw)*(tsncr/365) =	0.87	fraction
Total operating time for the SNCR (t _{op}) =	CF _{total} x 8760 =	7621	hours
NO _x Removal Efficiency (EF) =	(NO _x _{in} - NO _x _{out})/NO _x _{in} =	23	percent
NO _x removed per hour =	NO _x _{in} x EF x Q _B =	181.50	lb/hour
Total NO _x removed per year =	(NO _x _{in} x EF x Q _B x t _{op})/2000 =	691.62	tons/year
Coal Factor (Coal _F) =	1 for bituminous; 1.05 for sub-bituminous; 1.07 for lignite (weighted average is used for coal blends)	1.07	
SO ₂ Emission rate =	(%S/100)x(64/32)*(1x10 ⁶)/HHV =	< 3	lbs/MMBtu
Elevation Factor (ELEVF) =	14.7 psia/P =	1.07	
Atmospheric pressure at 1980 feet above sea level (P) =	$2116 \times [(59 - (0.00356 \times h)) + 459.7] / 518.6^{5.256} \times (1/144)^*$ =	13.7	psia
Retrofit Factor (RF) =	Retrofit to existing boiler	1.00	

* Equation is from the National Aeronautics and Space Administration (NASA), Earth Atmosphere Model. Available at <https://spaceflightsystems.grc.nasa.gov/education/rocket/atmos.html>.

Reagent Data:

Type of reagent used

Urea

Molecular Weight of Reagent (MW) = 60.06 g/mole
Density = 71 lb/gallon

Parameter	Equation	Calculated Value	Units
Reagent consumption rate (m_{reagent}) =	$(\text{NOx}_{\text{in}} \times Q_{\text{B}} \times \text{NSR} \times \text{MW}_{\text{R}}) / (\text{MW}_{\text{NOx}} \times \text{SR}) =$ (where SR = 1 for NH_3 ; 2 for Urea)	1540	lb/hour
Reagent Usage Rate (m_{sol}) =	$m_{\text{reagent}} / C_{\text{sol}} =$	3,080	lb/hour
	$(m_{\text{sol}} \times 7.4805) / \text{Reagent Density} =$	324.5	gal/hour
Estimated tank volume for reagent storage =	$(m_{\text{sol}} \times 7.4805 \times t_{\text{storage}} \times 24 \text{ hours/day}) / \text{Reagent Density} =$	109,100	gallons (storage needed to store a 14 day reagent supply rounded up to the nearest 100 gallons)

Capital Recovery Factor:

Parameter	Equation	Calculated Value
Capital Recovery Factor (CRF) =	$i (1+i)^n / (1+i)^n - 1 =$ Where n = Equipment Life and i= Interest Rate	0.0820

Parameter	Equation	Calculated Value	Units
Electricity Usage: Electricity Consumption (P) =	$(0.47 \times \text{NOx}_{\text{in}} \times \text{NSR} \times Q_{\text{B}}) / \text{NPHR} =$	110.9	kW/hour
Water Usage: Water consumption (q_{w}) =	$(m_{\text{sol}} / \text{Density of water}) \times ((C_{\text{stored}} / C_{\text{inj}}) - 1) =$	0	gallons/hour
Fuel Data: Additional Fuel required to evaporate water in injected reagent (ΔFuel) =	$H_v \times m_{\text{reagent}} \times ((1/C_{\text{inj}}) - 1) =$	1.39	MMBtu/hour
Ash Disposal: Additional ash produced due to increased fuel consumption (Δash) =	$(\Delta \text{fuel} \times \% \text{Ash} \times 1 \times 10^6) / \text{HHV} =$	28.4	lb/hour

Cost Estimate

Coal Creek SNCR w MNL Cost Estimate for 2019 BART - 0.10 lb NO_x/MMBtu

Total Capital Investment (TCI)

For Coal-Fired Boilers:

$$TCI = 1.3 \times (SNCR_{cost} + APH_{cost} + BOP_{cost})$$

For Fuel Oil and Natural Gas-Fired Boilers:

$$TCI = 1.3 \times (SNCR_{cost} + BOP_{cost})$$

Capital costs for the SNCR ($SNCR_{cost}$) =	\$4,230,857 in 2018 dollars
Air Pre-Heater Costs (APH_{cost})* =	\$0 in 2018 dollars
Balance of Plant Costs (BOP_{cost}) =	\$5,617,234 in 2018 dollars
Total Capital Investment (TCI) =	\$12,802,518 in 2018 dollars

* Not applicable - This factor applies only to coal-fired boilers that burn bituminous coal and emits equal to or greater than 0.3lb/MMBtu of sulfur dioxide.

SNCR Capital Costs ($SNCR_{cost}$)

For Coal-Fired Utility Boilers:

$$SNCR_{cost} = 220,000 \times (B_{MW} \times HRF)^{0.42} \times CoalF \times BTF \times ELEVF \times RF$$

For Fuel Oil and Natural Gas-Fired Utility Boilers:

$$SNCR_{cost} = 147,000 \times (B_{MW} \times HRF)^{0.42} \times ELEVF \times RF$$

For Coal-Fired Industrial Boilers:

$$SNCR_{cost} = 220,000 \times (0.1 \times Q_B \times HRF)^{0.42} \times CoalF \times BTF \times ELEVF \times RF$$

For Fuel Oil and Natural Gas-Fired Industrial Boilers:

$$SNCR_{cost} = 147,000 \times ((Q_B/NPHR) \times HRF)^{0.42} \times ELEVF \times RF$$

SNCR Capital Costs ($SNCR_{cost}$) =	\$4,230,857 in 2018 dollars
--	-----------------------------

Air Pre-Heater Costs (APH_{cost})*

For Coal-Fired Utility Boilers:

$$APH_{cost} = 69,000 \times (B_{MW} \times HRF \times CoalF)^{0.78} \times AHF \times RF$$

For Coal-Fired Industrial Boilers:

$$APH_{cost} = 69,000 \times (0.1 \times Q_B \times HRF \times CoalF)^{0.78} \times AHF \times RF$$

Air Pre-Heater Costs (APH_{cost}) =	\$0 in 2018 dollars
---	---------------------

* Not applicable - This factor applies only to coal-fired boilers that burn bituminous coal and emit equal to or greater than 3lb/MMBtu of sulfur dioxide.

Balance of Plant Costs (BOP_{cost})

For Coal-Fired Utility Boilers:

$$BOP_{cost} = 320,000 \times (B_{MW})^{0.33} \times (NO_x \text{ Removed/hr})^{0.12} \times BTF \times RF$$

For Fuel Oil and Natural Gas-Fired Utility Boilers:

$$BOP_{cost} = 213,000 \times (B_{MW})^{0.33} \times (NO_x \text{ Removed/hr})^{0.12} \times RF$$

For Coal-Fired Industrial Boilers:

$$BOP_{cost} = 320,000 \times (0.1 \times Q_B)^{0.33} \times (NO_x \text{ Removed/hr})^{0.12} \times BTF \times RF$$

For Fuel Oil and Natural Gas-Fired Industrial Boilers:

$$BOP_{cost} = 213,000 \times (Q_B/NPHR)^{0.33} \times (NO_x \text{ Removed/hr})^{0.12} \times RF$$

Balance of Plant Costs (BOP_{cost}) =	\$5,617,234 in 2018 dollars
---	-----------------------------

Annual Costs

Total Annual Cost (TAC)

$$\text{TAC} = \text{Direct Annual Costs} + \text{Indirect Annual Costs}$$

Direct Annual Costs (DAC) =	\$4,351,631 in 2018 dollars
Indirect Annual Costs (IDAC) =	\$1,055,568 in 2018 dollars
Total annual costs (TAC) = DAC + IDAC	\$5,407,198 in 2018 dollars

Direct Annual Costs (DAC)

$$\text{DAC} = (\text{Annual Maintenance Cost}) + (\text{Annual Reagent Cost}) + (\text{Annual Electricity Cost}) + (\text{Annual Water Cost}) + (\text{Annual Fuel Cost}) + (\text{Annual Ash Cost})$$

Annual Maintenance Cost =	$0.015 \times \text{TCI} =$	\$192,038 in 2018 dollars
Annual Reagent Cost =	$q_{\text{sol}} \times \text{Cost}_{\text{reag}} \times t_{\text{op}} =$	\$4,105,413 in 2018 dollars
Annual Electricity Cost =	$P \times \text{Cost}_{\text{elect}} \times t_{\text{op}} =$	\$30,510 in 2018 dollars
Annual Water Cost =	$q_{\text{water}} \times \text{Cost}_{\text{water}} \times t_{\text{op}} =$	\$0 in 2018 dollars
Additional Fuel Cost =	$\Delta \text{Fuel} \times \text{Cost}_{\text{fuel}} \times t_{\text{op}} =$	\$18,380 in 2018 dollars
Additional Ash Cost =	$\Delta \text{Ash} \times \text{Cost}_{\text{ash}} \times t_{\text{op}} \times (1/2000) =$	\$5,290 in 2018 dollars
Direct Annual Cost =		\$4,351,631 in 2018 dollars

Indirect Annual Cost (IDAC)

$$\text{IDAC} = \text{Administrative Charges} + \text{Capital Recovery Costs}$$

Administrative Charges (AC) =	$0.03 \times \text{Annual Maintenance Cost} =$	\$5,761 in 2018 dollars
Capital Recovery Costs (CR)=	$\text{CRF} \times \text{TCI} =$	\$1,049,806 in 2018 dollars
Indirect Annual Cost (IDAC) =	$\text{AC} + \text{CR} =$	\$1,055,568 in 2018 dollars

Cost Effectiveness

$$\text{Cost Effectiveness} = \text{Total Annual Cost} / \text{NOx Removed/year}$$

Total Annual Cost (TAC) =	\$5,407,198 per year in 2018 dollars
NOx Removed =	692 tons/year
Cost Effectiveness =	\$7,818 per ton of NOx removed in 2018 dollars

Principal Investigator
J. Muncy

This report describes research sponsored by EPRI.

The methodology described in this document was developed by Southern Company Services and modified, with permission, by EPRI. Individuals responsible for the development of the original Southern Company sulfuric acid model are Keith E. Harrison and Larry S. Monroe, Ph.D. of the Southern Company.

This publication is a corporate document that should be cited in the literature in the following manner:

Estimating Total Sulfuric Acid Emissions from Stationary Power Plants: 2018 Update. EPRI, Palo Alto, CA: 2018. 3002012398.

ABSTRACT

The U. S. Environmental Protection Agency's (EPA's) Toxics Release Inventory (TRI) program requires electric utilities to estimate and report annual emissions of 682 chemicals and chemical categories. Sulfuric acid (H_2SO_4) is one of the chemicals included in the TRI reporting requirement, when it is present in an aerosol form. The EPA defines sulfuric acid aerosols as "includ[ing] mists, vapors, gas, fog, and other airborne forms of any particle size." The objective of this report is to provide a method for predicting the sulfuric acid manufactured during fuel combustion, removed by air pollution control equipment or flue gas treatment, and released to the environment in stack gases. The estimation method is an empirical model, whereby emissions are predicted from factors derived from sulfuric acid measurements at full-scale power plants. The power generation units considered in the report include coal, oil and natural gas-fired boilers, as well as both simple and combined cycle gas turbines. The procedures presented here can be used to estimate sulfuric acid manufacture from combustion, operation of nitrogen oxide reduction control equipment and flue gas conditioning, and the removal of SO_3 or H_2SO_4 from the flue gas stream by air heaters, particulate control devices such as electrostatic precipitators (ESPs) and fabric filters, sulfur dioxide control equipment, and nitrogen oxide control equipment.

Deliverable Number: 3002012398

Product Type: Technical Update

Product Title: Estimating Total Sulfuric Acid Emissions from Stationary Power Plants: 2018 Update

PRIMARY AUDIENCE: Power company environmental staff responsible for Toxics Release Inventory reporting and air permitting.

SECONDARY AUDIENCE: Air quality agencies and other organizations with an interest in power plant emissions.

KEY RESEARCH QUESTION

The U. S. Environmental Protection Agency's (EPA's) Toxics Release Inventory (TRI) program requires owners of some coal-, oil-, and natural gas-fired power plants to estimate and report annual emissions of 682 chemicals and chemical categories. Sulfuric acid (H_2SO_4) is one of the chemicals included in the TRI reporting requirement, when it is present in an aerosol form. The objective of this report is to provide a method for predicting the sulfuric acid manufactured during fuel combustion, removed by air pollution control equipment or flue gas treatment, and released to the environment in stack gases.

RESEARCH OVERVIEW

The sulfuric acid estimation method is an empirical model, whereby emissions are predicted from factors derived from sulfuric acid measurements at full-scale power plants. The power generation units considered in the report include coal, oil, and natural gas-fired boilers, as well as both simple and combined cycle gas turbines. The procedures presented here can be used to estimate sulfuric acid manufacture from combustion, operation of nitrogen oxide reduction control equipment and flue gas conditioning, and the removal of SO_3 or H_2SO_4 from the flue gas stream by air heaters, particulate control devices such as electrostatic precipitators (ESPs) and fabric filters, sulfur dioxide control equipment, and nitrogen oxide control equipment. The 2018 update to this report incorporates modifications to the methodology for estimating emissions from coal plants with hot-side electrostatic precipitators (ESPs), and plants that add magnesium oxide to inhibit conversion of sulfur dioxide to sulfur trioxide.

KEY FINDINGS

- The principal sources of sulfuric acid emissions from fossil fuel-fired power plants are 1) oxidation of sulfur during fuel combustion, 2) injection of sulfur trioxide for flue gas conditioning to improve the efficiency of ESPs, and 3) increased conversion of sulfur dioxide to sulfur trioxide when flue gas passes through selective catalytic reduction (SCR) NO_x control equipment.
- Sulfuric acid is removed from flue gas when it reacts with ammonia to form solids that are not reportable to TRI, and are also removed when the flue gas passes through wet or dry scrubber equipment.
- Measurements of sulfuric acid before and after power plant process equipment were used to develop factors representing the impact of fuel type and pollution control devices on formation and removal of sulfuric acid.

WHY THIS MATTERS

Sulfuric acid is emitted from power plants that burn coal, and to a lesser extent, those that burn oil or natural gas for electricity production. For some U.S. power plants, the quantities emitted must be reported annually to the Environmental Protection Agency TRI program, as well as to state agencies. This report provides power plant owners with a methodology to estimate the impact of fuel changes or new equipment on sulfuric acid emissions.

HOW TO APPLY RESULTS

The equations in this report provide a complete methodology for estimating emissions from most common fossil fuel-fired power plant configurations. The equations may be calculated by entering them into a spreadsheet. The Electric Power Research Institute (EPRI) also incorporates the equations into the Toxics Release Inventory for Power Plants software, designed to assist power plant owners with annual TRI reporting.

INTRODUCTION

Background

Estimation of sulfuric acid emissions from power plants is a topic of increasing importance to the U.S. electric utility industry. Most significantly, Section 313 of the Emergency Planning and Community Right-to-Know Act (EPCRA), also known as the Toxics Release Inventory (TRI), requires facilities that “manufacture,” “process,” or “otherwise use” a listed chemical above certain threshold amounts to report their annual releases of the chemical to EPA and state agencies. For sulfuric acid, the TRI reporting requirements are triggered if a facility “manufactures” or “processes” more than 25,000 pounds of this chemical or “otherwise uses” more than 10,000 pounds of it in a given calendar year.

In June 1995, the U. S. Environmental Protection Agency (EPA) modified the list of chemicals subject to the EPCRA § 313 reporting requirements so that only aerosol forms of sulfuric acid would be subject to the TRI reporting requirements (EPA, 1995a). EPA defines sulfuric acid aerosols as “includ[ing] mists, vapors, gas, fog, and other airborne forms of any particle size.” Although initially it appeared that only liquid droplets of sulfuric acid needed to be reported, the present method estimates the sulfuric acid emissions regardless of the physical state of the molecules.

Beginning on July 1, 1999, certain coal- and oil-fired electric power plants have been required to report annual releases of TRI chemicals that they manufacture, process or otherwise use above threshold amounts. Under EPA’s EPCRA § 313 regulations, coal- and oil-fired electric utilities are deemed to “manufacture” sulfuric acid. Thus, electric utilities have to submit TRI reports on sulfuric acid aerosol releases if they “manufacture” more than 25,000 pounds of the chemical in a given reporting year (EPA, 1997).

Emissions of sulfuric acid received considerable attention in with the broad application of selective catalytic reduction (SCR) NO_x control technology. The use of SCR unavoidably contributes to production of sulfur trioxide (SO₃), the precursor of sulfuric acid. Several notable incidents have been witnessed where an increase in sulfuric acid emissions, as manifested by an increase in stack plume visibility, was attributed to the addition of SCR process equipment to an existing power plant. The deployment of approximately 115 GW of selective catalytic reduction (SCR) from 1997 through 2009 prompted power plant owners to conduct extensive measurements documenting the fate of SO₃ and sulfuric acid in power plants.

The methodology described in this report was developed by Southern Company Services (SCS). Between 2000 and 2005, SCS developed several versions of the estimation methodology and released draft reports informally (Hardman, 1998; Hardman, 1999; Monroe, 2001, Harrison, 2004, and Harrison, 2005). The SCS model was widely used in the electrical power generation industry for TRI reporting and other emissions estimation purposes. In 2007, EPRI received permission from Southern Company Services to modify the SCS estimation method to include additional data and improvements, and to publish this method under EPRI sponsorship. The 2008

version of the model added the ability to estimate emissions based on a specified sulfuric acid flue gas concentration at the stack, which can be used when alkali injection is employed to reduce sulfuric acid emissions. The 2010 version updated several of the “technology impact factors” (F2 factors, used to reflect the impact of pollution control devices on sulfuric acid releases) with new SO₃ measurements. The 2012 version of the model (EPRI, 2012) made minor changes to the calculation procedure to more accurately represent flow through from the boiler and control devices, changed the approach used to account for sulfuric acid from flue gas conditioning (FGC), and made several corrections and clarifications to technology factors, including a new technology factor for units with a wet electrostatic precipitator (ESP) and the addition of a new sulfuric acid source through the oxidation of sulfur dioxide across a carbon monoxide catalyst in combined cycle units.

The current version of the model makes minor changes to the application of the sulfuric acid removal factors (Technology Impact Factors, F2) for configurations that include a hot-side ESP or magnesium oxide addition to the fuel or furnace. This version also incorporates methodology for the calculation of releases when SCR or SCNR is only injected on a partial-year basis (previously published in 2014 as an erratum to the 2012 report).

Objective

The objective of this report is to present a methodology for estimating sulfuric acid emissions from power generating facilities, for use in Toxics Release Inventory reporting and other applications. The scope of units considered includes coal- and oil-fired steam generating units, as well as simple cycle and combined cycle natural gas- and oil-fired combustion turbines. To date, the most authoritative and documented data describe sulfuric acid emissions from coal-fired steam generators. The focus on this category of units is due to the increased availability of measurements describing the fate of sulfuric acid attributable to the retrofit of SCR process equipment on coal-fired steam generators.

Report Organization

Section 2 of this report addresses the uncertainty in measuring SO₃ concentration using the preferred controlled condensation system (CCS) method, and the accuracy and representativeness of the available data. Section 3 outlines the general methodology adopted in this model while Section 4 describes the details of the methodology, focusing on data that can be used to predict sulfuric acid manufacture by combustion. This section also summarizes data describing the removal of sulfuric acid across air heaters, ESPs, and wet flue gas desulfurization (FGD) process equipment. Section 5 outlines how to conduct the calculation for steam boilers firing a mixture of fuels. Section 6 addresses simple cycle and combined cycle combustion turbine applications. Example calculations for various power plant configurations are presented in Appendix A. A chronology of changes to the sulfuric acid model is presented in Appendix B.

2

MEASUREMENT UNCERTAINTY

A predictive method for sulfuric acid emissions requires knowledge of sulfuric acid production and the fate of emissions from specific boilers and combustion turbines, to an acceptable degree of measurement accuracy. In addition, a large database of measurements from many electric generating units (EGUs) is desired to obtain a robust predictive method. Both the size and the representativeness of the measurement database are critical to the accuracy of a predictive method.

The predictive correlations presented in this report are based on data obtained from field tests conducted predominantly within the last 10 years, with some estimates conducted in the 1990s. The quality of the data is thought to vary widely. It was not possible to obtain quality control information for all of the available measurements; thus, it was not possible to critically review all data used in this model.

The technique used to measure $\text{SO}_3/\text{H}_2\text{SO}_4$ is not known for all data sources, but most measurements were conducted using the controlled condensate system (CCS), a widely used technique that is generally considered the most accurate method for measuring $\text{SO}_3/\text{H}_2\text{SO}_4$ in stack gases from stationary combustion sources. EPA Method 8 is sometimes used for this purpose, but that method has a known positive bias from oxidation of SO_2 to SO_3 in the impinger solution.

CCS Measurement Uncertainty

A series of field and laboratory trials conducted by EPRI evaluated the measurement bias of the CCS technique by comparing results from both laboratory tests and field trials (EPRI, 2001). $\text{SO}_3/\text{H}_2\text{SO}_4$ measurements at similar gas compositions were compared in a 1) clean, ash-free laboratory environment; 2) simulated ash environment, and 3) actual field duty. The findings of the EPRI tests conducted under high-ash conditions are applicable to much of the field data used to derive removal factors in the current estimation model. The results showed that, when fly ash was present in the flue gas stream, the technique imposed a low bias (e.g., indicated lower $\text{SO}_3/\text{H}_2\text{SO}_4$ than measured in the ash-free laboratory environment), due to reactions of SO_3 or sulfuric acid with fly ash in the filter thimble holder upstream of the CCS condenser. Conversely, the EPRI tests indicated that use of CCS downstream of the particulate control device produces unbiased measurements, as long as appropriate procedures are followed.

The extent of bias observed in the EPRI study depended on the sampling location, which could be the air heater inlet, air heater outlet, or flue gas desulfurization outlet. Furthermore, the bias depended on the quantity of ash collected, the alkalinity of the ash, and the coal sulfur content (e.g., SO_2 content in the sample gas). Measurement bias in the simulated ash environment was observed for both high sulfur coal and low sulfur Powder River Basin (PRB) coal; however biasing in the PRB coal tests can generally be considered non-significant in light of already low SO_3 concentrations and the expected absorption of sulfuric acid with the alkaline ash in actual field tests. Data for high sulfur coal suggested a low bias of 20-25% could occur in measurement

locations upstream of a particulate control device with typical ash loadings, and no significant bias downstream of the particulate control device.

The precision of the CCS data used in this estimation model can be estimated from the variability among duplicate measurements believed to be conducted under the same process conditions. Data from recent field trials with experienced test crews suggest a precision of up to $\pm 20\%$ is realistic for most conditions. The repeatability of the CCS measurements depends on avoiding stratification within the gas stream (traversing is very difficult), maintaining correct temperatures in the sampling train, and having well trained sampling personnel. Therefore, the precision of the entire data set used in this model, which includes data from older studies of unknown quality, is expected to be closer to $\pm 50\%$.

Representativeness

The accuracy of the correlations presented in this report depends on the representativeness of the constituent data points. For some power plant configurations, only a few measurements are available, and the correlations provide only rough approximations of the flue gas $\text{SO}_3/\text{H}_2\text{SO}_4$ releases for similar units. The category with the largest number of data points is dry-bottom boilers, firing low sulfur, eastern bituminous coal. In general, the number of SO_3 measurements for various power plant configurations are proportional to the occurrence of those configurations among the total population of U.S. EGUs. The number of measurements in each power plant category should be considered when applying this model; factors based on one measurement have much higher uncertainty than factors based on dozens of measurements.

As a consequence of the uncertainty in $\text{SO}_3/\text{H}_2\text{SO}_4$ measurements and the limited number of data points that comprise the relevant correlations, the predictive technique should be assumed to provide estimates within a $\pm 50\%$ relative accuracy.

3

BACKGROUND AND METHODOLOGY OVERVIEW

This section provides a brief overview of sulfuric acid production mechanisms in power plants and presents the basic equations for estimating sulfuric acid releases. A detailed review of this topic has been provided by Srivastava (2004) and more recently by Monroe (2006).

The production or manufacture of SO_3 , and ultimately sulfuric acid, is determined initially by processes occurring directly within the flame zone of a boiler, the convective heat transfer sections, or environmental control components. These production or manufacturing processes can be gas phase or can be induced by catalysis on the surface of fly ash particles or heat removal surfaces.

Mechanisms that remove sulfuric acid from the flue gas also can occur both in the gas phase and on heat transfer surfaces, usually promoted by ash-derived deposits. The amount of sulfuric acid released from the stack is the aggregate result of production mechanisms, generally occurring at temperatures above 650°F , and removal mechanisms, including alkali-based sorbent injection, occurring at lower temperatures.

Description of General Methodology

The method estimates the manufacture and the subsequent release of sulfuric acid from the power generation process. The *manufacture* of sulfuric acid is defined as any process step that increases the flue gas content of sulfuric acid, regardless of its ultimate fate. To estimate the *release* of sulfuric acid, the manufacture estimate is corrected by a factor or series of factors to account for sulfuric acid removal within the system.

Three process steps ultimately lead to the manufacture of sulfuric acid in a fossil fuel-fired electricity generation unit: the combustion process, selective catalytic reduction (SCR) for NO_x control, and flue gas conditioning. All remaining steps in the power generation process reduce sulfuric acid. Therefore, the total sulfuric acid released (TSAR) is the cumulative sum of the total sulfuric acid manufactured (TSAM), adjusted by sulfuric acid losses.

Sulfuric Acid Manufacture from Combustion

A detailed analytical study by Senior (2002) explored details of SO_2 oxidation to SO_3 . Specifically, the author modeled the relevant reaction sets employing the temperature-time history of a typical utility boiler, considering gas phase events only and ignoring catalytic effects. The results showed that insignificant SO_3 formed in the early stage of the flame, but SO_3 production increased as the gases exited the flame zone and cooled. The author reported production of SO_3 to be essentially complete prior to flue gas entering the economizer section. The observation that most SO_3 forms during cooling from post-flame temperatures ($2,900$ - $3,100^\circ\text{F}$) to temperatures typical of the economizer entrance was also noted by Buckley (2002). Senior further quantified the relationship between coal sulfur content, excess air, and SO_3 production that has been empirically observed by previous investigators. Specifically, the results showed that after four seconds of residence time, SO_3 production could range from between 0.3 - 0.6% of the flue gas SO_2 concentration.

In the absence of SCR NO_x control or FGC, the boiler or turbine combustion process comprises the only source of sulfuric acid. The sulfuric acid manufacture by the combustion process (EM_{Comb}) is expressed as follows:

$$EM_{Comb} = K \bullet F1 \bullet E2 \quad \text{Eq. 3-1}$$

Where K is a constant, F1 is a Fuel Impact Factor describing the SO₃ production associated with combustion for a specific fuel type, and E2 is the annual rate of SO₂ production. Further details of this relationship and the derivation of constants and other terms are presented in Section 4. There are two situations where the TSAR equations must be modified to reflect reduction or removal of sulfuric acid from combustion: 1) the use of a hot-side ESP and 2) magnesium oxide (Mag-Ox) addition to the boiler or fuel. All other sources of sulfuric acid (SCR or FGC) are manufactured downstream of these two technologies and require no modifications. The derivation and use of technology impact factors for hot-side ESP and Mag-Ox addition are discussed in Section 4.

Sulfuric Acid Manufacture from SCR/SNCR NO_x Control

The SCR process increases the production of SO₃, and therefore, H₂SO₄, as a percentage of SO₂. SO₃ production can range from as low as 0.3%, for the most recent catalyst technology, to as high as 3% of the SO₂ concentration.

The production of SO₃ from SO₂ is a well-known consequence of SCR, and the degree of SO₂ oxidation is a performance variable that should be part of catalyst procurement specifications. To a degree, SO₃ production can be mitigated by reducing the content of vanadium pentoxide and compensating with other catalyst oxides such as tungsten or molybdenum, which offer improved selectivity (e.g., lower SO₂ oxidation) but also lower activity for NO_x removal. Alternatively, advanced catalyst formulations can be used that concentrate the vanadium-containing active ingredients on the catalyst surface and minimize content within the substrate, lowering SO₂ oxidation. To achieve an equivalent level of NO_x and residual ammonia slip, a low SO₂ oxidation catalyst may require a larger volume of catalyst than one for which SO₂ conversion is not constrained. In general, the degree of SO₂ oxidation ranges from about 0.2% to 1.5% for most SCR process reactors designed for bituminous coals. If SCR is applied to extremely low sulfur, high alkalinity coals such as PRB, higher SO₂ oxidation is acceptable. Depending on how the measurement of SO₂ oxidation is performed, the oxidation can be 3% or higher.

In many instances, owners and catalyst suppliers prefer that measurements to quantify SO₂ oxidation for the purpose of commercial guarantees be conducted not with authentic flue gas but in a laboratory-scale test facility, without fly ash present. This approach has the advantage of improved accuracy and repeatability of the SO₃ concentration. The measurements are generally conducted using CCS. However, particularly for PRB coals, this method will over-predict SO₃ manufactured by the SCR, as the mitigating role of high fly ash alkalinity is not considered. Consequently, the role of fly ash alkalinity must be considered in predicting SO₃ manufactured by SCR.

The observation that calculated laboratory-scale SO₃ values at the exit of an SCR reactor exceed measurements in the field has been witnessed on numerous occasions. Specifically, Lindenhoff (2004) reported that the measured SO₂ oxidation rate for PRB-generated flue gas of 1.25% was below the 1.6% value predicted based on the boiler and SCR catalyst specifications. Further,

tests conducted by this catalyst manufacturer noted significant absorption of SO₃ generated within the SCR reactor prior to the air heater. Sufficient data was accumulated to derive both a mathematical model and to project a graphical relationship describing SO₃ removal within an SCR reactor as a function of both ash content and the number of alkaline sites available in the flue gas stream.

An alternative NO_x control process, selective non-catalytic reduction (SNCR), does not use a catalyst and does not promote the oxidation of SO₂ to SO₃. Accordingly, there is no manufacture of sulfuric acid attributable to SNCR.

The following relationship describes the total H₂SO₄ manufactured from an SCR equipped utility boiler or steam generator:

$$EM_{SCR} = K \bullet S2 \bullet f_{sops} \bullet E2 \bullet F3_{SCR} \quad \text{Eq. 3-2}$$

Where K is a constant, S2 is the catalyst SO₂ oxidation rate, f_{sops} is the fraction of the coal burn in which flue gas is directed through the SCR, E2 is the annual rate of SO₂ production, and F3_{SCR} is the Technology Impact Factor for SCR used to adjust for the presence of alkaline fly ash. Further details of this relationship and the derivation of constants and other terms are presented in Section 4.

Sulfuric Acid Manufacture from Flue Gas Conditioning

Flue gas conditioning (FGC) is a process that is typically used in power plants to assist in particulate control in an ESP or baghouse. The conditioning additives can be any of the following: SO₃, SO₃ plus NH₃, or NH₃ alone. In SO₃-based FGC, SO₃ is introduced into the flue gas either preceding or following the air heater. The SO₃ is typically produced on-site from sulfurous fuel that is burned to produce SO₂, which is then catalytically oxidized to SO₃ with a conversion rate typically exceeding 95%. When injected into the flue gas, the SO₃ immediately reacts with water vapor to create sulfuric acid, thus resulting in the manufacture of sulfuric acid. Estimating the manufacture source requires knowledge of the concentration of SO₃ injected and the associated oxygen content of the flue gas.

Equation 3-3 estimates the manufacture of sulfuric acid from FGC, where K_e is a constant, B is the coal burn, f_e is the FGC operating factor, and I_s the SO₃ injection rate. F3_{FGC} is the Technology Impact Factor for FGC that is used to adjust for the presence of alkaline fly ash in PRB coals. Further details and derivation of the constant are provided in Section 4.

$$EM_{FGC} = K_e \bullet B \bullet f_e \bullet I_s \bullet F3_{FGC} \quad \text{Eq. 3-3}$$

Methodology to Estimate Release

Sources of sulfuric acid manufactured upstream of the air preheater are calculated separately (modified for hot-side ESP or Mag-Ox if necessary), then summed. The combined SO₃ is modified to reflect reactions of SO₃ with residual equivalent NH₃ slip from SCR/SNCR equipment and/or FGC ammonia injection to form ABS, and then adjusted by removal in applicable downstream equipment such as the air preheater, electrostatic precipitator or other particulate control device (PCD) and flue gas desulfurization (FGD) equipment. In the calculations to determine the amount of ABS formation, ammonia slip is subtracted from sulfuric acid. However, the 1:1 ratio of H₂SO₄ to NH₃ is on a molar basis. Therefore, all the following

calculations of ammonia slip are actually the amount of ammonia slip that is equivalent to sulfuric acid based on a 1:1 molar ratio, as determined through the use of the constant K. The adjustments are made using Technology Impact Factors (F2) which describe the fraction of sulfuric acid that penetrates each component.

The methodology employs the follow steps, combined into a single release equation, which is shown in Equation 3-4, and illustrated schematically in Figure 3-1:

1. Calculate the sources of sulfuric acid upstream of the APH from combustion, SCR and FGC
2. If applicable, apply the technology factor for sulfuric acid removal to the sulfuric acid manufactured from combustion only, for hot-side ESP and/or Mag-Ox addition
3. Sum the resulting sources of sulfuric acid upstream of the APH from combustion, SCR and FGC
4. Calculate residual equivalent ammonia slip from the SCR/SNCR and FGC and subtract this ammonia from the sum of the sources upstream of the APH to account for ABS formation which is not reportable
5. If the result of Steps 1) and 2) is a positive value, apply the technology factor for APH removal of SO₃ (F2_{APH})
6. Add downstream sources of sulfuric acid (from FGC, if injected downstream), and subtract downstream ammonia injection (from FGC, if injected downstream) to account for ABS, which is not reportable
7. Apply all remaining relevant downstream technology factors

In equation form, the methodology is expressed as shown in Equation 3-4.

$$\text{TSAR} = \{ [(\text{EM}_{\text{Comb}} * F2_{\text{Hotside_ESP}} * F2_{\text{Mag-ox}}) + \text{EM}_{\text{SCR/SNCR}} + \text{EM}_{\text{FGC_beforeAPH}}) - (\text{NH3}_{\text{SCR}} + \text{NH3}_{\text{FGC_beforeAPH}})] * F2_{\text{APH}} + (\text{EM}_{\text{FGC_afterAPH}} - \text{NH3}_{\text{FGC_afterAPH}}) \} * F2_x \quad \text{Eq. 3-4}$$

where,

TSAR	= Total sulfuric acid released
EM _{Comb}	= Sulfuric acid manufactured through combustion
EM _{SCR/SNCR}	= Sulfuric acid manufactured from SCR or SNCR
EM _{FGC_beforeAPH}	= Sulfuric acid manufactured from FGC injected upstream of the air preheater (APH)
EM _{FGC_afterAPH}	= Sulfuric acid manufactured from FGC injected downstream of the APH
NH ₃ Slip	= Calculated equivalent ammonia slip that reacts with H ₂ SO ₄ to form ammonium bisulfate (ABS) from SCR/SNCR and/or FGC
F2 _{APH}	= Technology Impact Factor for APH
F2 _{Hotside_ESP}	= Technology Impact Factor for hot-side ESP

	= 0.63 if hot-side ESP is present
	= 1.0 if hot-side ESP is <u>not</u> present (optional)
$F2_{Mag-Ox}$	= Technology Impact Factor for magnesium oxide addition in fuel or furnace
	= 0.25 (or custom) if Mag-Ox is sprayed into furnace
	= 0.50 (or custom) if Mag-Ox is mixed with fuel
	= 1.0 if Mag-Ox is <u>not</u> applied (optional)
$F2_x$	= Technology Impact Factors, all others that apply (downstream of APH)

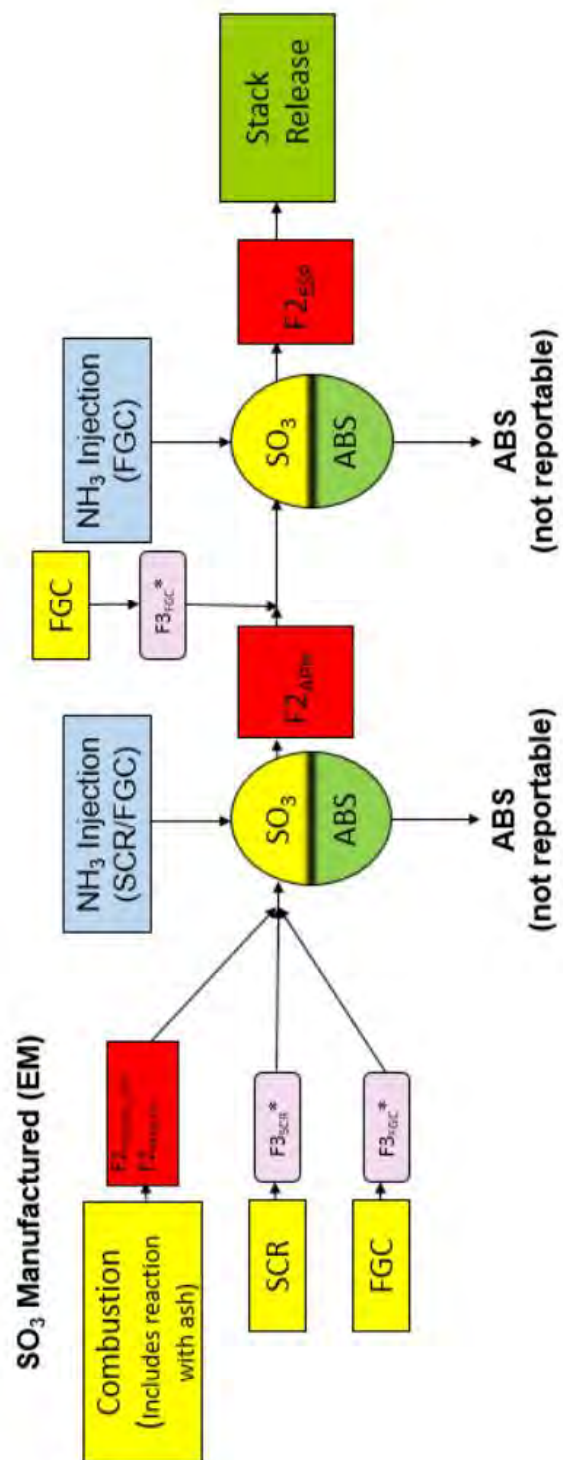

Figure 3-1
Schematic of Methodology Used to Estimate Sulfuric Acid Releases

Ammonia from SCR/SNCR NO_x Control

Both SCR and SNCR can introduce residual ammonia (NH₃), also called ammonia slip, into the flue gas. This residual ammonia can react with SO₃ or sulfuric acid to form ammonium sulfate and/or ammonium bisulfate, thereby removing from the flue gas some of the SO₃ that is a precursor to sulfuric acid, and reducing the amount released.

For an SCR, ammonia slip is expected to usually range between 0 and 2 parts per million (ppm) for bituminous coal cases. Higher values of ammonia slip are possible if the unit has not been recently tuned, the boiler or SCR process operates under upset, or as the catalyst ages. Higher ammonia slip may be tolerable in PRB coal applications, since ammonia is not readily absorbed by the highly alkaline PRB ash and adverse operational impacts (air preheater pluggage and ash contamination by ammonia) are avoided. Reactions between the residual ammonia and SO₃ or H₂SO₄ occur in the air preheater and result in a solid product that may deposit or accumulate on the surface of the fly ash. Any SO₃ or H₂SO₄ that participates in these reactions is no longer present as sulfuric acid and is not required to be reported to the EPA TRI program as a release of sulfuric acid.

SNCR employs ammonia or urea injection in the upper furnace for NO_x reduction. The higher temperatures characteristic of the upper furnace zone (1,800 to 2,400°F, as compared to 700°F for SCR) do not require reduction catalyst so there is no additional manufacture of SO₃ or sulfuric acid. Typically, SNCR systems operate with higher levels of residual ammonia (5 to 10 ppm), so any sulfuric acid that is present from combustion is reduced through reaction with the ammonia. Consequently, SNCR systems will always *reduce* the overall amount of sulfuric acid released, while SCR systems can *reduce* but will likely *increase* the amount of sulfuric acid released.

The reactions between SO₃ and/or H₂SO₄ and ammonia produce ammonium sulfate [(NH₄)₂SO₄] and/or ammonium bisulfate (NH₄HSO₄). While both chemicals are solids, the bisulfate pairs one molecule of ammonia with one of sulfuric acid, while the sulfate requires two ammonia molecules for each sulfuric acid. Which reaction product is present is usually determined by the stoichiometry, or the relative amount of each substance on a mole basis, that is present in the flue gas. When ammonia is present in an amount over twice the mole content of sulfuric acid, the reaction product will always be ammonium sulfate (AS). Conversely, when sulfuric acid is present in an amount on a mole basis greater than ammonia, the product will be ammonium bisulfate (ABS). Between these two extremes, a mixture of ammonium sulfate and bisulfate is produced.

A SCR-equipped unit firing bituminous coals with low-to-medium sulfur content will always produce an excess of sulfuric acid over ammonia slip. Accordingly, ammonium bisulfate is the primary byproduct anticipated. For subbituminous and lignite coals, any sulfuric acid produced is typically adsorbed by the ash and it is likely that residual ammonia will exceed sulfuric acid content on a mole basis. Under these conditions, ammonium sulfate is the likely product.

For SNCR-equipped units, ammonia slip levels of 5 ppm and possibly higher will favor ammonium sulfate, particularly for western U.S. coals where the alkaline fly ash will reduce the SO₃ content. For eastern bituminous coals, which have generally higher sulfur content and lower ash alkalinity, ammonium bisulfate will likely predominate.

For the purpose of predicting sulfuric acid emissions, these distinctions are not important. A single molecule of sulfuric acid will capture a single molecule of ammonia, producing ammonium bisulfate. If additional ammonia is available, the ammonium bisulfate can react with another ammonia molecule to form ammonium sulfate. It can be assumed that all sulfuric acid forms ammonium bisulfate before any further reaction to the ammonium sulfate form occurs. This assumption leads to the calculation strategy that ammonia captures all of the sulfuric acid it can as ammonium bisulfate, and since the bisulfate form is no longer reportable, the sulfuric acid disappears from the release calculation. Additional ammonia reacting with the ammonium bisulfate is of no consequence to the sulfuric acid calculation – although this reaction is important when estimating ammonia releases.

The total sulfuric acid released is reduced by the residual equivalent ammonia, or ammonia slip, from SCR or SNCR. This equivalent ammonia slip is calculated as follows, and is added to any ammonia injection from FGC before it is subtracted from the sum of the sulfuric acid manufactured.

$$\text{NH3}_{\text{SCR}} = K_s \bullet B \bullet f_{\text{sreagent}} \bullet S_{\text{NH3}} \quad \text{Eq. 3-5}$$

Where K_s is a constant, B is the coal burn in TBtu/yr, f_{sreagent} is the fraction of SCR operation with reagent injection, and S_{NH3} is the NH_3 slip for the SCR/SCNR. This calculation and factors are described further in Section 4.

Ammonia from Flue Gas Conditioning

Flue gas conditioning may involve injection of NH_3 alone or NH_3 with SO_3 . Thus, FGC can result in sulfuric acid manufacture or may result in sulfuric acid removal, if NH_3 is injected alone or in quantities greater than the sulfuric acid. The following equation describes the calculation of equivalent ammonia that is used to reduce sulfuric acid. If ammonia is injected upstream of the APH, this value would be added to the residual ammonia from SCR/SNCR. If added downstream of the APH, the value would be subtracted from any downstream SO_3 injection introduced by FGC.

$$\text{NH3}_{\text{FGC}} = K_e \bullet B \bullet f_e \bullet I_{\text{NH3}} \quad \text{Eq. 3-6}$$

Where K_e is a constant, B is the coal burn in TBtu/yr, f_e is the fraction of coal burn with FGC operation, and I_{NH3} is the NH_3 injected. This calculation and factors are described further in Section 4.

Estimating Release with Alkali Injection

Many utility operators inject alkali into the flue gas to control SO_3 . A wide variety of alkali materials based on calcium, sodium, or in some cases magnesium compounds, have been used with varying degrees of effectiveness to remove SO_3 . These alkali materials include sodium bisulfate, trona, and various types of lime (conventional, hydrated, and magnesium enhanced).

Sodium bisulfate (SBS) is the most widely used reagent for control of SO_3 . SBS is introduced into the flue gas, usually at the air heater exit, but in some units at the air heater inlet, to maximize residence time and improve SO_3 removal. SBS can be highly effective in removing SO_3 . Additional sodium can be added to the flue gas to compensate for any compromise in ESP

performance due to increased ash resistivity associated with SO₃ reduction. A detailed summary of experience with SBS usage has recently been published (Moser, 2007).

Trona is another sodium-containing reagent that is used to control SO₃. Trona can be injected at several locations within the boiler, but most applications introduce trona at the air heater exit, prior to the particulate collector (Ritzenthaler, 2006). As with SBS, additional sodium introduced into flue gas is advantageous to compensate for the reduction in ESP performance.

Several forms of calcium-based sorbents can be utilized. These are injected at various locations in the flue gas, including the economizer inlet, economizer outlet (e.g., air heater inlet), and the air heater outlet. A survey of recent experience with lime-derived sorbents addressed the advantages of this approach (Benson, 2006a). Hydrated lime has been shown to be an effective calcium-based reagent for SO₃ control (Gale, 2006), as has lime supplemented with magnesium hydroxide (Benson, 2006b). Calcium-based sorbents can be very effective in reducing SO₃, but may compromise ESP performance, as the reduced SO₃ content in flue gas increases the electrical resistivity of the ash on the collecting plate. For this reason, some operators have proposed using both calcium- and sodium-based sorbents, the latter to both augment SO₃ removal and promote ESP performance. In summary, any of several alkali materials can be used to control SO₃, with the least cost solution depending on the plant and access to low cost sorbent.

Plant units that deploy alkali injection will generally have conducted field tests to determine the SO₃ concentration in flue gas for a specified sorbent injection rate. In most cases, these tests will be conducted at the stack. The alkali injection system usually is operated to reduce SO₃ emissions to between 5 and 15 ppm, an optimal range to prevent formation of a visible plume. A procedure to convert measured sulfuric acid concentration in flue gas to a mass emission rate is summarized below and described in more detail in Section 4. An example application of this procedure is provided in Appendix A.

$$ER_{ALKINJ} = K_{alkali} \bullet B \bullet S_{SO_3} \bullet F_{2x} \bullet F_{alkali} \quad \text{Eq. 3-7}$$

Where K_{alkali} is a constant, B is the coal burn, S_{SO_3} is the measured SO₃ content with injection, F_{alkali} is the fraction of time alkali injection is in operation, and F₂ are any applicable downstream Technology Impact Factors.

Users of this approach should be cautioned that the current EPA-approved test method for SO₃ (EPA Method 8) has a significant positive bias, and that corrections for this bias may be needed to accurately assess flue gas concentrations. A more accurate method is the controlled condensate system (CCS). Although no general-purpose, EPA-approved CCS method is currently available, it is widely used by stack test contractors for sulfuric acid measurement and is more accurate than Method 8, if performed correctly.

Some units will not have measured stack emissions. This version of the model adds an alternate approach to estimate releases with alkali injection if stack SO₃ measurements are not available. Instead of using Equation 3-7 for ER_{ALKINJ} , the total sulfuric acid release is calculated by estimating total releases using Equation 3-4. An alkali injection factor, $F_{3ALKINJ}$, is then applied to the total release as shown in Equation 3-8. This $F_{3ALKINJ}$ is either the expected fractional reduction in SO₃ (generally as guaranteed by the vendor) or a default of 0.2. The basis of the 0.2 value is test results indicating that 80% removal is easily achievable (EPRI, 2010b). This method is explained in further detail in Section 4.

$$TSAR_{ALKINJ} = (TSAR_{Comb+SCR+FGC}) \bullet F3_{ALKINJ}$$

Eq. 3-8

To estimate SO₃ manufacture with alkali injection, plant owners should use the standard approaches given in Section 4 for the appropriate plant configuration. At this time, EPRI does not have sufficient information to estimate the impact on SO₃ formation of adding alkali at various points in the fuel combustion and stack gas treatment process. Assuming that there is no reduction of SO₃ formation is conservative for a threshold determination for TRI reporting purposes.

Estimating Sulfuric Acid with Partial-Year SNCR or SCR Operation

When ammonia or urea is employed in SCR or SNCR during only part of a year, the methodology outlined in this report may not provide an accurate estimate of total sulfuric acid released through the stack. The reason is that the model calculates the pounds of ammonia injected on an annual basis, and uses that quantity to subtract an equivalent quantity of sulfuric acid as non-reportable ammonia salt. However, if there is an excess of ammonia slip present during SCR/SNCR operation above the amount of SO₃ available to react, the model is in effect borrowing SO₃ from periods when the SCR/SNCR is not operating. As a result, the annual release of sulfuric acid will be underestimated for that unit. Underestimation of sulfuric acid releases is most likely to when the following conditions are met:

- SNCR (more likely) or SCR (less likely) operated partial-year
- Sulfuric acid emissions are calculated from fuel sulfur, not CEMS
- The operating factor for reagent addition in the SCR/SNCR system ($f_{sreagent}$) is small
- The unit burns a fuel that inherently manufactures low levels of SO₃ from combustion, such as PRB coal
- The unit has high ammonia slip levels when ammonia is injected

To determine whether the model is underestimating releases for a unit with SCR or SNCR partial-year operation, the user should perform separate calculations for the SCR/SNCR “Ammonia On” condition and SCR/SNCR “Ammonia Off” condition, allocating the amount of fuel burned during the two conditions appropriately. If the sum of the sulfuric acid releases for these two conditions is greater than for the full-year calculation, separate calculations should be employed going forward.

4

ESTIMATING GUIDELINE: STEAM BOILERS

This section describes an estimation procedure for calculating the manufacture and release of sulfuric acid from coal-fired steam generators. The topics addressed are (a) formation within the furnace; (b) the role of SCR, (c) flue gas conditioning (FGC), and (d) alkali injection; and (e) removal by downstream equipment such as air heaters, ESPs or other particulate control devices, and FGD process equipment. Each of the subsequent sections in this chapter provides the information to conduct this stepwise calculation.

Sulfuric Acid Manufacture

Sulfuric Acid Manufactured by Combustion (EM_{Comb})

The premise of the methodology is that the amount of sulfuric acid manufactured by the boiler is a function of the amount of SO_2 produced – which may be determined either from coal usage (amount burned and sulfur content) or from continuous emission monitoring system (CEMS) output. Units equipped with FGD equipment or other methods of SO_2 control are required to estimate emissions either from coal data or from the output of a CEMS positioned ahead of the scrubber. As described below, it may be necessary to correct SO_2 CEMS data for non-ideal stack flow conditions.

The following relationship is used to estimate the sulfuric acid manufactured from combustion in utility sources:

$$EM_{Comb} = K \bullet F1 \bullet E2 \quad \text{Eq. 4-1}$$

where,

- | | | |
|-------------|---|---|
| EM_{Comb} | = | total H_2SO_4 manufactured from combustion, lbs/yr |
| K | = | Molecular weight and units conversion constant |
| | = | $98.07 / 64.04 \bullet 2000 = 3,063$ |
| | | 98.07 = Molecular weight of H_2SO_4 |
| | | 64.04 = Molecular weight of SO_2 |
| | | 2000 = Conversion from tons per year to pounds per year. |
| F1 | = | Fuel Impact Factor |
| E2 | = | Sulfur dioxide (SO_2) emissions, either: (1) recorded by a continuous emissions monitor, tons/yr, or (2) calculated from coal burn data, tons/yr. |

The Fuel Impact Factor (F1) is a numerical value or a mathematical relationship reflecting the conversion of SO_2 to SO_3 in the boiler for a specific coal type and boiler type. In the derivation of Equation 4-1, the following assumptions are made:

- SO₃ concentrations are proportional to SO₂ concentrations.
- The grade of coal being burned impacts the rate of conversion from SO₂ to SO₃.
- All SO₃ that forms is converted to H₂SO₄.
- The rate of SO₃ formation is independent of the boiler firing rate (unit load).

The estimates of sulfur dioxide emissions (E2) and F1 factors are further described in the following sections.

Sulfur dioxide (SO₂) Emissions from Combustion (E2)

Estimating the sulfuric acid production from Equation 4-1 requires knowledge of the mass rate of SO₂ generated. This rate is designated as E2 in Equation 4-1. As noted previously, the value of E2 can be estimated from either (a) the EPA CEMS data, or (b) calculated from the coal burn data (EPA, 1995a).

If the CEMs data are used to directly quantify the annual SO₂ production rate in tons/year of SO₂, it may be necessary to correct for stack geometry, depending on the measurement method used. The user should check with their CEMs operator to obtain the bias correction factors, or the bias corrections may already be taken care of in the instrument software.

If a facility used EPA Methods 1 and 2 for CEM flow monitor setup and validation under the guidelines described in 40 CFR Part 60, Appendix A, flow bias and wall effects corrections should be made to the CEMs SO₂ measurements to accurately estimate sulfuric acid releases. This correction can be made using one of the following two equations:

$$E2 = E \left[1 - \frac{(C1 \cdot R^2 + C2 \cdot R + C3)}{100} \right] \quad \text{Eq. 4-2}$$

where,

- E2 = Corrected SO₂ mass rate, tons per year
- E = CEMS-derived SO₂ mass rate, tons per year
- C1 = 0.0264 (non-axial flow bias factor)
- C2 = 0.183 (non-axial flow bias factor)
- C3 = 1.5 (wall effects bias factor) – default value for cylindrical stacks
- R = Stack/duct average resultant angle (or swirl angle) from site verification tests, degrees

The average resultant angle, R, is determined using Method 1. The wall effects bias factor, C3, is the percent difference between flow rates calculated using standard Method 1 sampling and flow rates calculated using measured near-wall velocity data. Many utilities do not have bias data

available, and as such, an average default value of 1.5, derived from actual data, can be used. Measured bias factors were within the range of 0.9 to 2.2% (Noble, 1998).

If a facility used EPA Method 2H (EPA, 1999) for round stacks, or CTM-041 (EPA, 2003) for rectangular stacks to determine a Wall Adjustment Factor (WAF), then this value can be used instead and the correction equation can be simplified to the following:

$$E2 = E \bullet WAF \quad \text{Eq. 4-3}$$

where,

E2 = Corrected SO₂ mass rate, tons per year

E = CEMS-derived SO₂ mass rate, tons per year

WAF= Wall Adjustment Factor, determined from Method 2H

The WAF correction factor determined by Method 2H is applicable to stack flow rates determined by Methods 2, 2F and 2G. A default value of 0.995 can be used, although actual data should be used if available.

As an alternative to using CEMS data, the following relationship based on coal burn data can be used to estimate the rate of SO₂ emissions:

$$E2 = K1 \bullet K2 \bullet C1 \bullet S1 \quad \text{Eq. 4-4}$$

where,

E2 = SO₂ mass rate, tons/yr

C1 = Dry coal burn, tons/yr. The dry coal can be calculated from wet coal through the following relationship:

Dry coal (tons/yr) = wet coal (tons/yr) • (1-moisture(%)/100%)

S1 = Coal sulfur weighted average, %, dry

K1 = Molecular weight and units conversion constant

= (64.04)/(100 • 32.06) = 0.02

64.04 = molecular weight of SO₂

32.06 = molecular weight of S

100 = conversion of % S to a fraction

K2 = Sulfur conversion to SO₂, implicit from EPA AP-42 (EPA, 1995b)

= 0.95 for bituminous coals

= 0.875 for subbituminous coals

= 0.55 to 0.85 for lignite, based on the Na content

= 1.0 for oil

When any source uses FGD equipment or another technology to control SO₂ emissions, either the fuel basis must be used for the manufacturing and release calculations, or CEMS data can be used, but only when the CEMS precedes the FGD or SO₂ control equipment. Data from a CEMS located after a flue gas desulfurization system cannot be used, because the measured SO₂ has already been decreased by the control equipment, and therefore is not an accurate predictor of the SO₃ emissions rate.

Fuel Impact Factor (F1). Figure 4-1 depicts the fraction of H₂SO₄ produced as a function of flue gas SO₂ content for several coal sources and boiler types. The coal ranks and boiler types consist of (a) high sulfur (>2.5%) eastern bituminous coal, fired in a dry bottom boiler (wall-fired or cell-fired), (b) low sulfur eastern bituminous coal, fired in a dry bottom boiler, (c) PRB coal, fired in both a cyclone and dry bottom boilers. Data are also shown for one unit that fires 75% lignite with the balance PRB and one unit that fires 100% lignite.

Figure 4-1 shows that a wide range in SO₃ production is observed for all coals and boiler types. This range exceeds the theoretical predictions by Senior (2000), suggesting that the role of ash in either catalyzing SO₃ production or absorbing/neutralizing SO₃ is not fully accounted for. The only consistent results in Figure 4-1 are for SO₃ from PRB-fired units, regardless of boiler type, in that less than 1 ppm was observed.

The current model uses a linear relationship to estimate SO₃ production for all eastern bituminous, dry bottom boiler data, as shown in Figure 4-1. The equation expressing this relationship is shown in Equation 4-5. This relationship is significant at the 95% confidence level, although the correlation coefficient (R²) is low (0.13) due to scatter in the data. The current model retains F1 factors based on average fraction of SO₂ converted to SO₃ for all other coal types.

Figure 4-1
Relationship between Boiler SO₃ Production and Flue Gas SO₂ (corrected to 3% O₂)

$$F1_{\text{ebit}} = 1.12\text{E-}6 \bullet \text{SO}_2 + 0.0065 \quad \text{Eq. 4-5}$$

where,

$F1_{\text{ebit}}$ = Fuel Impact Factor for all Eastern Bituminous coals burned in a dry-bottom boiler

SO_2 = Boiler SO₂ concentration (ppm), derived from fuel sulfur content (%)

In order to use this approach, it is necessary to relate coal sulfur (%) to the SO₂ concentration in the boiler. Equation 4-6 is used to calculate that relationship:

$$\text{SO}_2 = S1 \bullet \frac{K_{F1}}{HV} \quad \text{Eq. 4-6}$$

where,

SO_2 = Boiler SO₂ concentration (ppmvd, 3% O₂, dry) derived from fuel sulfur content (%)

$S1$ = Coal sulfur weighted average, %, dry

K_{F1} = Conversion factor = 10,003,602

HV = Coal heating value, Btu/lb, dry

The conversion factor K_{F1} considers all relevant constants to yield the result in ppm of SO_2 . The derivation of this constant is presented in Text Box A.

Text Box A: Derivation of Conversion Factor, K_{F1} . The U.S. Code of Federal Regulations 40, Part 60, Table 19-1 “F Factors for Various Fuels” states that 1 million Btu of heat input for bituminous or subbituminous coal will produce 10,640 wet standard cubic feet of flue gas, defined at 0% oxygen and on a wet basis at 20°C and 760 mm Hg. Correcting this volume to 3% O_2 on a dry basis (typical of the SO_2 measurement data used in the Fuel Impact Factors correlation) yields a volume of 11,419 scf. The standard volume of one pound mole of any gas is 359 scf, defined at 0°C and 760 mm Hg. Converting this to the English units standard of 20C (68°F), one pound mole occupies 385.5 standard cubic feet. The value 0.95 is the AP-42 (EPA, 1995b) K2 factor for sulfur conversion to SO_2 for a bituminous coal.

Equation 4-4 above can then be expanded as follows:

S1%	0.95	385.5 scf S	1 lb mol S	1 MBtu	1 lb fuel	10^6 Btu	10^6 ppm
	100%	1 lb mol S	32.06 lbs S	11,419 scf	HV Btu	1 MBtu	

Grouping terms,

$$SO_2 = S1 \bullet 10,003,602 / HV$$

Therefore, the value of K_{F1} is equal to $10,003,602$ [ppmvd SO_2 (3% O_2 , dry) • Btu/lb]/%S.

Table 4-1 summarizes the F1 factors. There are no changes to these factors from the previous version of the model (EPRI, 2012).

Table 4-1
Summary of Fuel Impact (F1) Factors for Steam Generating Units

Fuel	Equipment	F1	Comment
E. Bituminous (all) ¹	Dry Bottom Boiler	Slope: 1.1163E-6 Intercept: 0.0064877	F1 = slope SO ₂ + intercept 32 data points

¹For eastern bituminous coal, a linear relationship between SO₂ and SO₃ is used instead of an average F1 factor.

Sulfuric Acid Manufactured from SCR (EM_{SCR})

This section describes a method to estimate impacts of SCR on sulfuric acid emissions. As discussed in Section 3, SCR produces SO_3 (and ultimately sulfuric acid), while SNCR removes or reduces it due to the reaction with residual ammonia. As such, only the SCR process will be addressed in this section. The removal equations will be discussed in subsequent sections, and will address both SCR and SCNR, as residual ammonia from either process contributes to sulfuric acid removal.

The following relationship estimates the total H_2SO_4 manufactured from an SCR equipped utility boiler or steam generator:

$$EM_{SCR} = K \bullet S2 \bullet f_{sops} \bullet E2 \bullet F3_{SCR} \quad \text{Eq. 4-7}$$

where,

EM_{SCR} = Total H_2SO_4 manufactured from SCR, lbs per year

K = Molecular weight and units conversion constant
= $98.07 / 64.04 \bullet 2000 = 3,063$

98.07 = Molecular weight of H_2SO_4

64.04 = Molecular weight of SO_2

2000 = Conversion from tons per year to pounds per year.

$S2$ = SCR catalyst SO_2 oxidation rate (specified as a fraction, typically from 0.001- 0.03)

f_{sops} = Operating factor of SCR system, or the fraction of coal burn when the flue gas is directed through the SCR, whether NH_3 reagent is injected to derive NO_x reduction or not. This value should reflect the hours the SCR reactor processed flue gas, which will be site-specific but can be approximated by generally 0.8 for year-round peaking operation, 0.98 for year-round base-loaded operation, or 0.43 for seasonal operation

$E2$ = SO_2 produced, tons per year

$F3_{SCR}$ = Technology Impact Factor, for SCR

The Technology Impact Factor for SCR ($F3_{SCR}$) is required to adjust SO_3 content for the presence of alkaline fly ash, as described in Section 3, unless direct measurements exist for the subject unit documenting SO_3 increase across the SCR reactor.

It is important to select the correct SO_2 oxidation rate, $S2$, for use in Equation 4-7. Typically, the SO_2 oxidation rate from SCR catalysts can range from as low as 0.3% of flue gas SO_2 content, up to 3% for low sulfur, highly alkaline coals (e.g., PRB). There are two means by which SO_2 oxidation is specified and measured for SCR process equipment, and each has significantly different implications for SO_3 produced. One method – based on actual field tests in commercial units – does not require adjustment and can be used as reported to predict sulfuric acid. The other method is based on laboratory tests of catalyst samples in the absence of ash and alkaline

materials, and must be adjusted to account for these latter factors. The consequences of each of these methods on estimates of sulfuric acid emissions are described as follows:

Full-Scale Catalyst Performance Tests. Ideally, SO₂ conversion data will be determined with commercial testing of full-scale equipment. These data – measured on commercial plants under actual operating conditions – are the most authentic in reflecting actual SO₃ content, as the impact of ash alkalinity is taken into account. This approach reflects commercial process operation, and the resulting fractional oxidation rate can be used as the S2 value in Equation 4-7 without adjustment by the F3_{SCR} Technology Impact Factor.

Laboratory Bench-Scale Tests. Some owners and process suppliers prefer to specify and conduct guarantee measurements for SO₂ oxidation on laboratory-scale equipment using synthetic flue gases without fly ash. There are good reasons to select this methodology; evidence suggests SO₃ measurements in the environment of the test laboratory are more accurate and reproducible than field tests. However, this method does not expose the catalyst being tested to ash, so there is no alkaline component to mitigate or absorb any SO₃ generated. Accordingly, SO₂ oxidation reported by this method exceeds that measured in commercial practice, particularly for PRB coals. SO₂ oxidation data from bench-scale tests can be used, but must be adjusted for the role of ash alkalinity. This adjustment is provided by the Technology Impact factor F3_{SCR}.

Table 4-2 shows the F3_{SCR} factors. It should be noted that the 0.17 factor for PRB coals when using laboratory-scale SO₂ conversion (S2) data without fly ash is based on measurements at two PRB-fired units. SO₃ emitted from these units was lower than specified in the catalyst guarantee, which was based on laboratory test data. At present, there are no data to support F3_{SCR} factors for other coals, so a factor of 1 (full penetration) is recommended. Additionally, if full-scale catalyst performance SO₂ conversion data is used, the F3_{SCR} factor is 1 for all coal types.

Table 4-2
F3_{SCR} Technology Impact Factors for SCR

Coal Type	F3 _{SCR}
Using Laboratory-Scale SO ₂ Conversion Data (S2), Without Fly Ash	
PRB	0.17 (n = 2)
Other Coals	1 (no data available)
Using Full-Scale Catalyst Performance SO ₂ Conversion Data (S2)	
All Coals	1

SNCR does not result in the manufacture of sulfuric acid; thus, EM_{SNCR} for SNCR is by definition zero.

Sulfuric Acid Manufactured from FGC (EM_{FGC})

In order to moderate ash resistivity, most SO₃-based FGC systems attempt to maintain a fixed concentration of SO₃ in the flue gas, typically between 5 and 7 ppm by volume (ppmv). Calculations to estimate the sulfuric acid manufactured during FGC use the setpoint of the FGC system as the key input. The FGC system is assumed to operate during most of the plant's duty, except for perhaps startup and low load operation. The sulfuric acid manufactured by SO₃-based FGC equipment (EM_{FGC}) is calculated as follows:

$$EM_{FGC} = K_e \bullet B \bullet f_e \bullet I_s \bullet F3_{FGC}$$

Eq. 4-8

where,

- EM_{FGC} = Total H_2SO_4 manufactured from FGC, lbs per year, either upstream of APH ($EM_{FGC_beforeAPH}$) and/or downstream of APH ($EM_{FGC_afterAPH}$)
- K_e = Conversion factor = 3,799, see Text Box B.
- B = Coal burn in TBtu/yr
- f_e = Operating factor of FGC system: the fraction of coal burn when the FGC system operates. This value is site-specific, must be determined for each unit, but generally will be about 0.8.
- I_s = SO_3 injection rate in ppmv at 6% O_2 , wet; generally,
 - = 7 ppmv if before the APH
 - = 5 ppmv if after the APH
- $F3_{FGC}$ = Technology Impact Factor for FGC
 - = 0.17 for PRB coal
 - = 1 for all other coals

A Technology Impact Factor for FGC ($F3_{FGC}$) is used to adjust the flue gas SO_3 manufacture from FGC injection to account for the presence of alkaline fly ash. The principle is the same as for the $F3_{SCR}$ factor that is used to adjust the flue gas SO_3 produced by SO_2 oxidation rate on the SCR catalyst.

The method first reduces the SO_3 that is injected into a PRB-fired boiler using the $F3_{FGC}$ factor to account for sorption by the alkaline fly ash. Subsequently, SO_3 from FGC is treated the same as all other sources of sulfuric acid with respect to ABS formation or reduction through control devices. The $F3_{FGC}$ factor (0.17) is assumed to be equal to the $F3_{SCR}$ factor. A $F3_{SCR}$ of 1.0 is used for eastern bituminous coals (zero reduction), as those coals produce an acidic ash that does not adsorb appreciable amounts of SO_3 .

The conversion factor K_e , equal to 3,799, considers all relevant constants to yield the result in pounds per year of sulfuric acid. The derivation of this constant, for the case where residual SO_3 is reported in terms of 6% oxygen and “wet” flue gas at 8.1% H_2O , is presented in Text Box B.

Text Box B: Derivation of Conversion Factor, K_e . The U.S. Code of Federal Regulations 40, Part 60, Table 19-1 “F Factors for Various Fuels” lists that 1 million Btu of heat input for bituminous or subbituminous coal will produce 10,640 wet standard cubic feet of flue gas, defined at 0% oxygen and on a wet basis at 20°C and 760 mm Hg. Correcting this volume to 6% O_2 (typical at ESP conditions) yields a volume of 14,925 scf. The standard volume of one pound mole of any gas is 359 scf, defined at 0°C and 760 mm Hg. Converting this to the English units standard of 20°C (68°F), one pound mole occupies 385 standard cubic feet. Using these in the equation above,

$$(K_e \bullet B \bullet f_e \bullet I_s) = \text{lbs H}_2\text{SO}_4 \text{ per yr} =$$

B TBtu	$I_s(\text{S}_{\text{NH}_3})$ scf NH_3	1 lb mol SO_3	1 lb mol H_2SO_4	98 lbs H_2SO_4	14925 scf fg	10^6 MBtu
year	10^6 scf flue gas	385 scf SO_3	1 lb mol NH_3	1 lb mol H_2SO_4	1 MBtu	TBtu

Grouping terms,

$$= B \bullet f_e \bullet I_s \bullet 3,799$$

Therefore, the value of K_e is equal to 3,799 lbs H_2SO_4 /(TBtu • ppmv SO_3 @ 6% O_2 and wet).

Equation 4-8 specifies the concentration of SO_3 in flue gas (I_s) in terms of ppmv at 6% O_2 , wet flue gas basis. If the concentration of SO_3 is reported at different conditions, the value of the constant K_e will change. The following formula is used to adjust the value of the constant K_e :

$$K_e (\text{O}_2, \text{H}_2\text{O}) = 3,799 (6\% \text{O}_2, 8.1\% \text{H}_2\text{O}) \bullet [(100-8.1)/(100-\text{new H}_2\text{O})] \bullet [(20.9 - 6.0)/(20.9 - \text{new O}_2)] \quad \text{Eq. 4-9}$$

For example, if the SO_3 concentration is quantified at a value (in ppm) that is defined at 0% oxygen and a dry basis, the value of K_e that should be used is:

$$K_e (\text{O}_2, \text{H}_2\text{O}) = 3,799 (6\% \text{O}_2, 8.1\% \text{H}_2\text{O}) \bullet [(100-8.1)/(100-0)] \square [(20.9 - 6.0)/(20.9 - 0)]$$

$$K_e = 2,489$$

The sulfuric acid manufacture from FGC should be noted as either upstream of the APH, $\text{EM}_{\text{FGC_beforeAPH}}$, or downstream of the APH, $\text{EM}_{\text{FGC_afterAPH}}$. These values must be kept separate for the release equations.

FGC equipment that employs NH_3 injection alone does not manufacture sulfuric acid and therefore this amount, EM_{FGC} , would be zero. However, the injected NH_3 will reduce the total

release of sulfuric acid by reacting with SO₃ or the resultant H₂SO₄, and therefore should be used in the release equation, as discussed in subsequent sections.

Total Manufacture from All Sources

The total manufacture of sulfuric acid is the sum of the individual manufacture estimates, prior to any adjustments or modifications due to fuel conditioning or particulate devices. Therefore, if a site burns coal and uses both SCR and FGC, the amount of sulfuric acid manufactured – by combustion, SCR, and/or FGC – is summed to determine the total amount.

Accordingly, total sulfuric acid manufacture (TSAM) is estimated for a generating unit equipped with SCR and flue gas conditioning by the following equation:

Total Sulfuric Acid Manufacture (TSAM) is described by the following equation:

$$\text{TSAM} = \text{EM}_{\text{Comb}} + \text{EM}_{\text{SCR}} + (\text{EM}_{\text{FGC_beforeAPH}} + \text{EM}_{\text{FGC_afterAPH}}) \quad \text{Eq. 4-10}$$

Sulfuric Acid Release

Both SCR and/or ammonia-based FGC may have a negative effect on sulfuric acid release, as the ammonia slip can combine with some or all of the sulfuric acid generated from combustion to form a non-reportable ammonia salt (ABS or AS). Under these conditions, ammonia-based FGC can serve to only reduce the release of sulfuric acid. Therefore, sources of ammonia are calculated in terms that are equivalent on a 1:1 molar basis as sulfuric acid, summed in relation to the APH, and used to adjust the sulfuric acid manufactured. Once adjusted by the equivalent ammonia, the remaining sulfuric acid is then adjusted by the removals in applicable downstream equipment such as the APH, ESP or other particulate control device and FGD equipment by applying Technology Impact Factors (F₂) which describe the fraction of sulfuric acid that penetrates each component.

Total Sulfuric Acid Release (TSAR) is described by the following equation:

$$\text{TSAR} = \{ [((\text{EM}_{\text{Comb}} * F2_{\text{HotSide_ESP}} * F2_{\text{Mag-ox}}) + \text{EM}_{\text{SCR}} + \text{EM}_{\text{FGC_beforeAPH}}) - (\text{NH3}_{\text{SCR}} + \text{NH3}_{\text{FGC_beforeAPH}})] * F2_{\text{APH}} + (\text{EM}_{\text{FGC_afterAPH}} - \text{NH3}_{\text{FGC_afterAPH}}) * F2_{\text{x}} \} \quad \text{Eq. 4-11}$$

where,

TSAR	= Total Sulfuric Acid Release, lbs per year
EM _{Comb}	= Total sulfuric acid manufactured from combustion, lbs per year
F _{2HotSide_ESP}	= Technology Impact Factor for hot-side ESP = 0.63 if hot-side ESP is present = 1.0 if hot-side ESP is <u>not</u> present (optional)
F _{2Mag-Ox}	= Technology Impact Factor for magnesium oxide addition in fuel or furnace = 0.25 (or custom) if Mag-Ox is sprayed into furnace

	= 0.50 (or custom) if Mag-Ox is mixed with fuel	
	= 1.0 if Mag-Ox is <u>not</u> applied (optional)	EM_{SCR} = Total sulfuric acid manufactured from SCR, lbs per year
$EM_{FGC_beforeAPH}$	= Total sulfuric acid manufactured from FGC upstream of the APH	
$EM_{FGC_afterAPH}$	= Total sulfuric acid manufactured from FGC downstream of the APH	
$NH3_{SCR}$	= Total equivalent ammonia slip produced from SCR/SNCR, lbs per year	
$NH3_{FGC_beforeAPH}$	= Total equivalent ammonia produced from FGC upstream of the APH, lbs per year	
$NH3_{FGC_afterAPH}$	= Total equivalent ammonia produced from FGC downstream of the APH, lbs per year	
$F2_{APH}$	= Technology Impact Factor for APH, applied only if subtotal for releases upstream of the APH is non-negative	
$F2_x$	= Technology Impact Factors for processes downstream of the APH, all that apply	

Examples in Appendix A detail the use of these calculations. Ammonia produced from SCR/SNCR and FGC are calculated using equations from the sections below.

The application of the hot-side ESP and Mag-Ox F2 factors to the sulfuric acid manufactured from combustion are a change from all previous versions of the report where these factors were applied to the total sulfuric acid release, which also included sulfuric acid from flue gas conditioning and SCR/SNCR. However, as a hot-side ESP removes sulfuric acid upstream of the APH, and therefore prior to any subsequent manufacture of sulfuric acid via SCR or FGC, the hot-side ESP F2 factor should only be applied to EM_{COMB} . Furthermore, application of magnesium oxide compounds into the furnace or fuel has been shown to only affect sulfuric acid produced from combustion, and does not affect any downstream formation due to SCR oxidation (Blythe, 2004). These two factors are discussed in more detail in subsequent sections, but it should be noted that as with other devices, these F2 factors only need to be included if the technology or device is present, and are optional (i.e. equal to 1.0) if the technology is not present.

The F2 factor for the APH ($F2_{APH}$) should only be applied if the subtotal of the sum of the sulfuric acid manufactured minus the ammonia slip upstream of the APH [$((EM_{Comb} * F2_{HotSide_ESP} * F2_{Mag-ox}) + EM_{SCR} + EM_{FGC_beforeAPH}) - (NH3_{SCR} + NH3_{FGC_beforeAPH})$] is a positive value. If this subtotal is negative, this would indicate that excess ammonia slip is still present after all the sulfuric acid from combustion, SCR and FGC has been consumed to form ABS. In this instance, the resulting ammonia slip should not be reduced by the $F2_{APH}$ factor, as all the ammonia is expected to penetrate the APH. This negative ammonia slip value can then be added to any downstream FGC injection, as summarized in Equation 4-12:

$$TSAR_{ExcessNH3} = \{ [((EM_{Comb} * F2_{HotSide_ESP} * F2_{Mag-ox}) + EM_{SCR} + EM_{FGC_beforeAPH}) - (NH3_{SCR} + NH3_{FGC_beforeAPH})] + (EM_{FGC_afterAPH} - NH3_{FGC_afterAPH}) \} \bullet F2_x \quad \text{Eq. 4-12}$$

Text Box C summarizes calculations for a unit equipped with a FGD process that employs partial flue gas bypass, to account for the fact that the entire flue gas flow is not subject to sulfuric acid removal by the FGD process. This bypass factor is pertinent only to units that employ flue gas bypass.

Text Box C: Flue Gas Desulfurization Bypass Calculation. Those units equipped with scrubbers where some of the flue gas bypasses the scrubber should take this into account in their total release calculations. No credit for sulfuric acid removal should be taken for the fraction of the flue gas that bypasses the scrubber. Therefore, this amount of the flue gas should not be multiplied by the F2 factor for the scrubber. However, the flue gas volume should still be multiplied by the F2 factors for the other control devices.

Modified equations considering partial scrubber bypass are given below and should be used where appropriate.

$$TSAR_{bypass} = \{[(EM_{Comb} + EM_{SCR/SNCR} + EM_{FGC_beforeAPH}) - (NH3_{SCR} + NH3_{FGC_beforeAPH})] \bullet$$

$$F2_{APH} + (EM_{FGC_afterAPH} - NH3_{FGC_afterAPH})\} \bullet F2_x$$

$$TSAR = [SB_f + (1 - SB_f) \bullet F2_s] \bullet TSAR_{bypass}$$

where, SB_f = fraction of scrubber bypass, as a decimal

$F2_s$ = F2 for scrubber

$F2_x$ = All other applicable F2 factors except for scrubber.

Ammonia Slip from SCR and SNCR ($NH3_{SCR}$)

A key assumption in the calculation methodology is that residual ammonia from either a SCR or SNCR captures all available sulfuric acid in the (ammonium) bisulfate form. The bisulfate form is not reportable under the Toxics Release Inventory rules and thus is not part of the manufacture calculation. If any additional ammonia reacts with bisulfate to form ammonium sulfate, that reaction is of no consequence to the sulfuric acid calculation – although it needs to be taken into account when estimating ammonia releases.

The total sulfuric acid released from combustion, SCR, and FGC is determined by subtracting from the sulfuric acid manufactured the amount removed by the residual ammonia, or equivalent ammonia slip, as calculated on a 1:1 molar basis with sulfuric acid. For SCR/SNCR, the ammonia slip is calculated using the following:

$$NH3_{SCR} = K_s \bullet B \bullet f_{sreagent} \bullet S_{NH3} \quad \text{Eq. 4-13}$$

where,

$NH3_{SCR}$ = Total equivalent ammonia slip produced from SCR/SNCR, lbs per year

K_s = Conversion factor = 3799, which is equivalent to K_e (See Text Box B)

B = Coal burn in TBtu/yr

$f_{sreagent}$ = fraction of SCR operation with reagent injection, when residual NH_3 is produced that will remove SO_3 . The value of $f_{sreagent}$ will be similar to, but slightly less than, the value of f_{sops} , defined for Equation 4-6.

S_{NH3} = NH_3 slip from SCR/SNCR, ppmv at 6% O_2 , wet:

- SCR averages 0.75 ppmv over catalyst guarantee period
- SNCR averages 5 ppmv
- Note: actual NH₃ slip data should be used if available

The conversion factor K_s, equal to 3,799, is equivalent to the factor K_e used for SO₃ injected from FGC, and considers all relevant constants to yield the result in pounds per year of equivalent ammonia. The derivation of this constant, in the form of K_e, was presented previously in Text Box B.

Equation 4-13 specifies the concentration of NH₃ in flue gas (S_{NH3}) in terms of ppmv at 6% O₂, wet flue gas basis. If the concentration of NH₃ is reported at different conditions, the value of the constant K_s will change. As with K_e, Equation 4-9, described previously and repeated again below for reference, is used to adjust the value of the constant K_s:

$$K_s (O_2, H_2O) = 3799 (6\% O_2, 8.1\% H_2O) \bullet [(100-8.1)/(100-\text{new } H_2O)] \bullet [(20.9 - 6.0)/(20.9 - \text{new } O_2)] \quad \text{Eq. 4-9}$$

The operating factor of the SCR describes the portion of the coal burn that reflects the period of SCR operation, based on whether the unit operates seasonally (0.43), annually in a base-load duty (0.98), or annually in peaking duty (0.80).

The coal burn rate in TBtu/yr can be obtained from coal use records, such as those reported to EIA in Form 767, or can be calculated from the annual coal burn (tons/yr) and the heating value of the coal, as described in the equation below:

$$B = C1 \bullet HV \bullet K_B \quad \text{Eq. 4-14}$$

where,

- B = Coal burn in TBtu/yr
- C1 = Dry coal burn, tons/yr. The dry coal can be calculated from wet coal through the following relationship:
Dry coal (tons/yr) = wet coal (tons/yr) • (1-moisture(%)/100%)
- HV = Coal heating value, Btu/lb, dry
- K_B = Conversion factor = 2E-9. The factor is calculated from the conversion of tons per year to pounds per year and Btu to TBtu (2000/10¹² = 2E-9)

Ammonia Injection from FGC (NH₃_{FGC})

Similar to reactions with ammonia slip from SCR or SNCR, any ammonia injected from FGC will react with sulfuric acid manufactured to form ABS. The following equation is used to calculate equivalent ammonia from FGC. Care must be taken to note the location of the ammonia injection, upstream or downstream of the APH, such that the ammonia can be utilized correctly in the release equation.

$$NH3_{FGC} = K_e \bullet B \bullet f_e \bullet I_{NH3} \quad \text{Eq. 4-15}$$

where,

- NH_{3FGC} = Total equivalent ammonia produced from FGC, lbs per year, either upstream of APH, $NH_{3FGD_beforeAPH}$, or downstream of APH, $NH_{3FGC_afterAPH}$
- K_e = Conversion factor = 3,799, as described in Text Box B
- B = Coal burn in TBtu/yr
- f_e = Operating factor of FGC system, or the fraction of fuel burn when the FGC system operates. This value will be the same as f_e described previously and in many cases can be approximated by 0.8.
- I_{NH_3} = NH_3 injection for dual flue gas conditioning, ppmv at 6% O_2 , wet; generally 3 ppmv NH_3 if operating, or zero (0) if no ammonia is used.

Total Release Calculation for Sources Employing Alkali Injection

As described in Section 3, sources that employ alkali injection to mitigate stack opacity or a visible plume will typically have access to field measurements describing SO_3 concentration in flue gas, most likely at the stack. The concentration of SO_3 measured at the stack can be converted to a mass emission rate using Equation 4-16.

$$ER_{ALKINJ} = K_{alkali} \bullet B \bullet S_{SO_3} \bullet F_{2x} \bullet F_{alkali} \quad \text{Eq. 4-16}$$

where,

- ER_{ALKINJ} = Total H_2SO_4 released from unit equipped with alkali injection, lbs per year
- K_{alkali} = Constant, equal to 3,799, which is equivalent to K_e , as described in Text Box B.
- B = Coal burn in TBtu/yr
- S_{SO_3} = SO_3 content, as measured in the stack or particulate collector exit, ppmv at 6% O_2 , wet
- F_{alkali} = Operating factor for the alkali injection system, fraction of coal burn when unit is operated with alkali addition to remove SO_3
- F_{2x} = Technology Impact Factors, to be applied only if SO_3 measurements are conducted at a location preceding the stack. The value of F_{2x} is 1 if measurements are conducted at the stack, and there are no control components downstream of the measurement location. If the control device is an SO_2 scrubber, F_{2x} is denoted as F_{2s} , but is handled the same way.

If the SO_3 content (S_{SO_3}) is known at conditions other than 6% O_2 and wet, Equation 4-8 can be used to calculate a new value K_{alkali} at the new conditions.

The Technology Impact Factors selected should represent the control equipment between the point of SO_3 measurement and the stack. For example, if a unit is equipped with only an ESP,

and the SO₃ measurement is conducted at the ESP inlet, then the F₂ factor for an ESP (Table 4-5, below) should be selected.

If the utility employing alkali injection does not have access to measured data, the total sulfuric acid releases may be calculated as described by Equation 4-11 (i.e., by estimating and summing the manufacture and applying the technology Impact Factors), and an alkali injection factor, F_{3ALKINJ}, is then applied to the total release. This F_{3ALKINJ} is either the expected fractional reduction in SO₃ (generally as guaranteed by the vendor), a default value of 0.2, as available data indicates 80% removal is easily achievable (EPRI, 2010b).

$$ER_{ALKINJ} = (TSAR_{Comb+SCR+FGC}) \bullet F_{alkali} F_{3ALKINJ} \quad \text{Eq. 4-17}$$

where,

- ER_{ALKINJ} = Total H₂SO₄ released from unit equipped with alkali injection, lbs per year
- TSAR_{Comb+SCR+FGC} = Total H₂SO₄ released from combustion, SCR and FGC, as calculated using Equation 4-10.
- F_{alkali} = Operating factor for the alkali injection system, fraction of coal burn when unit is operated with alkali addition to remove SO₃
- F_{3ALKINJ} = Technology Impact Factor for alkali injection; the expected fractional reduction in SO₃ (generally as guaranteed by the vendor). If no vendor information is available, use a default value of 0.2.

Partial Year Injection

If alkali injection is not utilized for the entire operating year (F_{alkali} does not equal 1), then Equation 4-16 (or Equation 4-17) must be added to the fraction of the total sulfuric acid release (TSAR) calculated from combustion, SCR/SNCR and/or FGC for the remainder of the operating time (Equation 4-11). Furthermore, in the calculation of TSAR for partial-year alkali injection, if SO₃ measurements also exist for operation without alkali injection, these data should be used with Equation 4-16 instead of the standard estimation equations, as shown below:

$$ER_{NOINJ} = K_{alkali} \bullet B \bullet S_{SO3} \bullet F_{2x} \bullet (1 - F_{alkali}) \quad \text{Eq. 4-18}$$

where,

- ER_{NOINJ} = Total H₂SO₄ released from unit without alkali injection, lbs per year
- K_{alkali} = Constant, equal to 3,799, which is equivalent to K_e, as described in Text Box B.
- B = Coal burn in TBtu/yr
- S_{SO3} = SO₃ content without alkali injection, as measured in the stack or particulate collector exit, ppmv at 6% O₂, wet

- F_{alkali} = Operating factor for the alkali injection system, fraction of coal burn when unit is operated with alkali addition to remove SO_3
- F_{2x} = Technology Impact Factors, to be applied only if SO_3 measurements are conducted at a location preceding the stack. The value of F_{2x} is 1 if measurements are conducted at the stack, and there are no control components downstream of the measurement location. If the control device is an SO_2 scrubber, F_{2x} is denoted as F_{2s} , but is handled the same way.

Accordingly, total sulfuric acid release (TSAR) for a unit employing partial-year alkali injection is estimated by one of the following equations:

$$\text{TSAR} = \text{ER}_{\text{ALKINJ}} + (\text{TSAR}_{\text{Comb+SCR+FGC}}) \cdot (1 - F_{\text{alkali}}) \quad \text{Eq. 4-19}$$

$$\text{TSAR} = \text{ER}_{\text{ALKINJ}} + \text{ER}_{\text{NOINJ}} \quad \text{Eq. 4-20}$$

Technology Impact Factors (F2)

The sulfuric acid estimating methodology employs empirically-derived Technology Impact Factors (F2). These F2 factors describe sulfate removal observed over the air heater, the ESP or other particulate control device, and FGD process equipment. Background information on these processes and the derivation of these F2 factors are addressed in this section.

Air Heater

The removal of SO_3 and/or H_2SO_4 within the air heater is due to the condensation of sulfuric acid and its removal as discrete individual particles (along with the fly ash) on the surface of this heat exchanger. The conventional Ljungstrom-type air heater has been documented to provide a removal sink for sulfuric acid (Saranuc, 1999). In fact, the largest supplier of Ljungstrom air heaters has evaluated the feasibility of employing the air heater process environment in conjunction with limestone injection as a proactive sulfuric acid control strategy (Hamel, 2003, and Bowes, 2006).

Air heater surfaces follow a pattern of alternately heating and cooling as the heat exchange elements move from the relatively hot flue gas to the cooler combustion air. As reported during field tests of commercial equipment (Saranuc, 1999), this temperature profile introduces a strong gradient in sulfuric acid concentration across the exit plane of the air heater. The cyclic thermal conditions as described by Hamel (2003) reveal that a significant portion of the air heater basket surface metal is exposed to flue gas temperature below the sulfuric acid dewpoint. This phenomenon may promote sulfuric acid deposition on the heat exchanger metal surface, compared to a tube-type heat exchanger in which the metal temperature is always above the sulfuric acid dewpoint.

Figure 4-2 presents data obtained from a survey of power plant operators and general literature sources describing $\text{SO}_3/\text{H}_2\text{SO}_4$ removal (and the corresponding F2 factors) across commercial, Ljungstrom-type air heaters. These data are presented as a function of SO_2 content of the flue gas for the host unit. Most data shown are for low sulfur eastern bituminous coal, for which air heater H_2SO_4 removal varies significantly between 0% and 69%, averaging 50% as indicated by the horizontal line. Two high sulfur (>2.5%) eastern cases are shown, along with limited data for PRB coal.

The data point showing 0% removal at approximately 600 ppm SO₂ is believed suspect, as an identical companion unit firing the same coal exhibited sulfuric acid capture of 38%. This measurement was not included in the F2 calculation.

Figure 4-2 presents two points reported by Hamel (2003) based on a low sulfur eastern bituminous-fired unit where SO₃ was “spiked” into the flue gas to elevate the concentration entering the air heater to 80 and 122 ppm. These two points are plotted separately on Figure 4-2 versus an estimated flue gas SO₂ content that could generate such values (using the average SO₂ oxidation rate for high sulfur, eastern bituminous coal in Figure 4-1. It should be noted these values measured for the “spiked” flue gas significantly exceed those measured for the two high sulfur eastern coal cases.

Figure 4-2
Removal of Sulfuric Acid by Ljungstrom-Type Air Heaters

The F2 factor for the air heater, calculated as $[1 - \text{Percent Removal}]$, is estimated excluding the “spiked” SO₃ and suspect 0% removal measurement. The F2 factors for the air heater for low sulfur eastern bituminous, medium-high sulfur eastern bituminous, and PRB coals are shown in Table 4-4. Data are not currently available for other coal types. For those coals, as well as fuel oils, the model user could consider adopting the F2 factor for PRB if the ash is strongly alkaline and the low sulfur, eastern bituminous value if the ash is acidic.

Table 4-3
Summary of F2 Factors for Air Heater Removal of Sulfuric Acid

Boiler Type	Fuel	F2	Standard Deviation	Comment
All Boilers	Low S Eastern Bit	0.50	0.15	Average of measurements at 7 units.
All Boilers	Med-High S Eastern Bit (S >2.5%)	0.85	n/a	Based on two data points.
All Boilers	PRB	0.36	n/a	Based on two data points.

The standard deviation of the reported measurements for low sulfur eastern bituminous coal is about one third of the average measurement. Inadequate data prevent calculating a standard deviation for F2 factors for the other fuels.

Particulate and SO₃ Control Processes

This section discusses the available data on removal of SO₃ by ESPs, FGDs, and alkali injection.

ESPs and Baghouses

An ESP provides extended residence time at relatively low temperatures, allowing contact between sulfuric acid and fly ash particles, as well as having collecting plates that can retain sulfuric acid particles. These features contribute to the removal of sulfuric acid. The ESP is the flue gas contacting device with perhaps the longest residence time; for large units, usually 10 seconds and in some cases, up to 15 seconds. Given the low flue gas velocities of 2 to 4 actual feet per second (0.6 – 1.2 meters per second), and the opportunity for heat loss at or near the walls, sulfuric acid condensation can be significant.

Figure 4-3 plots sulfuric acid removal by the ESP and the corresponding F2 factors as a function of the SO₂ content of the flue gas for the host unit, from a survey of plant operators. Most data shown are for a cold-side ESP and low sulfur eastern bituminous coal; three data points are shown for high sulfur coal (>2.5%). Also shown is a single data point for a hot-side ESP and four data points for low sulfur eastern bituminous coal. Similar to the case for the air heater, the 0% sulfuric acid removal at approximately 800 ppm SO₂ is suspect, as a companion unit at the same site firing the identical coal had 50% sulfuric acid removal. Accordingly, this “zero” removal datum, although shown in Figure 4-3, is not used in the analysis.

The F2 factor for the cold-side ESP, calculated as [1- Percent Removal], is estimated using all data except the 0% removal point. The F2 factors for ESP capture for low sulfur eastern bituminous, medium-high sulfur eastern bituminous, and PRB coals are listed in Table 4-5. Data are not currently available for other coal types. Western subbituminous coals (e.g., non-PRB) could consider adopting the F2 factor for PRB if the ash is strongly alkaline; western coals with acidic ash (e.g., bituminous) may consider adopting the low sulfur, eastern bituminous value. This guidance also applies to for fuel oils or any other coal that is not listed in the table.

Data describing the reduced H₂SO₄ penetration for one hot-side ESP (ESPh) is based on only a single test series. It should be noted that although this F2 factor is used for all coals, the measurement is from a power plant burning a low-sulfur, eastern bituminous coal. Comparison of F2 factors for a cold-side ESP burning low and high sulfur eastern bituminous coals show a

significant difference between the two coal types. As a result, total H_2SO_4 releases for hot-side ESP configurations may have a low bias; however, there is insufficient data to recommend alternate values.

Wet ESP's operate in much the same manner as a traditional ESP; however, due to the lower operating temperature and saturated environment, higher power levels are achievable, resulting in higher collection efficiency for sulfuric acid mists. Data describing sulfuric acid removal for a Wet ESP is based on two sets of paired measurements, both of which demonstrated 88% removal. One data point was from a high sulfur, eastern bituminous, coal-fired boiler and the other from a petroleum-coke fired boiler. Flue gas SO_2 was not reported for these tests; therefore, the data points are not included in Figure 4-3. Until further data are available, EPRI recommends using a wet ESP F2 factor of 0.12 for all fuels.

Baghouses show high H_2SO_4 removal based on very limited data. The average of two data points is 90% removal.

Figure 4-3
Removal of Sulfuric Acid by Cold-Side ESPs and One Hot-Side ESP

Table 4-4
Summary of F2 Factors for Particulate Control Devices (ESP, Baghouse)

Equipment Type	Coal Type	F2 Factor	Standard Deviation	Comment or Observation
Cold-side ESP	Low S Eastern Bit	0.63	0.15	Average of measurements at 4 units.
Cold-side ESP	High S Eastern Bit (>2.5%)	0.77	0.13	Average of measurements at 3 units.
Cold-side ESP	Subbituminous (PRB)	0.72	n/a	Based on one measurement at one unit.
Hot-side ESP	All	0.63	n/a	Based on one measurement at one unit.
Wet ESP	All	0.12	n/a	Average of measurements at two units
Baghouse	Subbituminous coal	0.10	n/a	Two data points.

n/a – not applicable – too few points to calculate.

The standard deviation of the reported measurements for low sulfur eastern bituminous coal is about one fourth of the average measurement, while the standard deviation of the measurements for the high sulfur eastern bituminous coal is about one sixth of the average. Inadequate data prevent calculating a standard deviation for F2 factors for the other fuels.

FGD

FGD process equipment rapidly cools or quenches flue gas, condensing a significant portion of the sulfuric acid into submicron droplets that can escape the process environment, confounding capture. Buckley (2002) notes that for condensation to occur, sulfuric acid generally must be supersaturated. However, fly ash particles can provide a nucleus for condensation of sulfuric acid, even at conditions that are not thermodynamically supersaturated. Buckley also projects sulfuric acid condensation on surfaces where equipment walls are lower in temperature than the flue gas (common in commercial equipment). However, the thin laminar boundary layer at the wall limits mass transfer, and for FGD equipment this mechanism provides no appreciable removal. Ironically, it is the high saturation conditions in this laminar layer near surfaces that are key to producing fine sulfuric acid mist.

Srivastava (2004) suggests that the condensed submicron droplets, once formed, are sufficiently small so that they follow the flow streamlines and avoid contact with the remaining wetted walls, liquid sheets, and droplets in the flow path. Although some degree of sulfuric acid removal is observed in FGD equipment, the amount is highly variable and depends on the design of the system. Buckley (2002) estimates FGD equipment removes 40-70% of the sulfuric acid, and Srivastava an average of 50%.

Figure 4-4 summarizes data reported in the public domain and from utility-specific tests describing FGD removal (and corresponding F2 factors) of sulfuric acid. The percent of sulfuric acid removal is depicted as a function of FGD inlet SO₂ concentration. Removals range from 14% to 78%, with an average of about 50%. The shaded portion of Figure 4-4 represents the upper and lower bounds of the data reported by Buckley (2002), while the solid horizontal line reflects the average reported by Srivastava (2004).

Table 4-6 summarizes the F2 factors for FGD process equipment, including results for a wet spray tower burning bituminous coal, and also one burning a blend of PRB/lignite. Given the limited data, the latter is assumed to serve as the basis of an F2-factor for 100% firing of PRB or lignite. Data for a wet venturi -type combined particulate/FGD process is also available, but only for a bituminous coal. Similar to the case for a wet spray tower, the lack of data merits assuming sulfuric acid removal for all coals is described by that measured for bituminous coal.

F2 factors for the use of magnesium-based additives in oil-fired boilers are also included in Table 4-6. These additives are used to control furnace slagging caused by the vanadium in the oil or to control sulfuric acid emissions or both. The fuel oil vanadium can also catalyze SO_2 to SO_3 oxidation, but the additive, when added to the oil, tends to effectively bind up the vanadium, partially reducing its catalytic effect. Addition of magnesium-based additives in the fuel oil tend to be less effective in controlling the emissions of sulfuric acid than the same additive sprayed into the furnace downstream of the flame zone. The factors for Mag-Ox addition are derived from a single data point; as such, it is recommended to use measured facility data if available

Figure 4-4
Removal of Sulfuric Acid by Flue Gas Desulfurization Equipment: Various FGD Designs, Coals

Table 4-5
Summary of F2 Factors for Wet and Dry FGD Equipment and Additives

FGD Type	Coal Type	F2 Factor	Standard Deviation	Comment or Observation
Wet: Spray Tower	E. Bituminous	0.47	0.17	Seven data points.
Wet: Spray Tower	PRB or Lignite	0.40	n/a	Two data points.
Wet: Venturi Tower	All coals	0.73	0.13	Four data points from three units, bituminous coal only; limited data merit assigning same factor for other coals.
Dry FGD and baghouse	All coals	0.01	n/a	Two data points.
Mg-Ox mixed w/fuel oil	All fuel	0.50	n/a	One data point.
Mg-Ox into furnace	All fuel	0.25	n/a	One data point.

5

ESTIMATING GUIDELINE: MULTIPLE FUEL OR BLENDED FUEL BOILERS

Estimating sulfuric acid production of steam boilers firing multiple or blended fuels – such as natural gas, fuel oil, and perhaps coal – uses the same approach as for single fuels. This will consist of determining the contribution of each source (combustion, SCR or SNCR NO_x control, and FGC) for each different fuel, and adjusting for loss or removal. It is assumed for multiple fuel boilers that the contribution of each fuel can be separated and treated individually. The same approach is to be used for boilers that fire a blended coal. This assumption is particularly important when considering blends of PRB with low or high sulfur eastern bituminous coal, as this approach accounts for the role of alkalinity in PRB ash in mitigating SO₃.

This approach of treating blends of coal as separate fuels in proportion to the mass burn rate is believed to be conservative with regard to SO₃ emissions when considering PRB coal, in that it will likely project H₂SO₄ emissions higher than actual. The ability of PRB coal to neutralize SO₃ by an amount that is greater than a direct proportion of the coal blend is due to the extremely high content of alkaline material, particularly CaO. However, data to quantify this impact with any reasonable degree of confidence are not available at present. Accordingly, the conservative approach is to presume an impact in direct proportion to the coal blend until a database can be developed.

The sequence of calculations is performed for the first component of the blend, including calculations for SCR and FGC, if applicable. The sequence is repeated for each component. When complete, the total manufacture of sulfuric acid is calculated by adding all of the manufacture totals for all fuels from all processes. Likewise, the release is summed over all processes and fuels.

As an example, if a unit with an SCR and FGC burns mostly coal, but uses natural gas in a NO_x reburn process and also disposes of used oil by combustion in the furnace, then the following sequence of calculations would be required:

1. Coal fuel
 - a. Combustion manufacture
 - b. Combustion release
 - c. SCR manufacture
 - d. SCR release
 - e. FGC manufacture
 - f. FGC release
2. Natural gas
 - a. Combustion manufacture
 - b. Combustion release
 - c. SCR manufacture

- d. SCR release
- e. FGC manufacture
- f. FGC release
- 3. Used oil
 - a. Combustion manufacture
 - b. Combustion release
 - c. SCR manufacture
 - d. SCR release
 - e. FGC manufacture
 - f. FGC release
- 4. Sum manufacture and releases
 - a. Manufacture

$$= 1a + 1c + 1e + 2a + 2c + 2e + 3a + 3c + 3e$$
 - b. Release

$$= 1b + 1d + 1f + 2b + 2d + 2f + 3b + 3d + 3f$$

All of the manufactured results would be summed together and the releases summed also to give the final result. Example 8 in Appendix A details this calculation procedure.

6

ESTIMATING GUIDELINE: COMBUSTION TURBINES

Natural gas-fired sources typically have negligible content of sulfur in the fuel, thus sulfuric acid production is negligible. Facilities that burn only natural gas are not required to participate in the TRI reporting program. However, sources that are co-located with coal units will need to be included in the estimates for total sulfuric acid release for the site. The calculation described in this section can also be used to estimate sulfuric acid emissions for Prevention of Significant Deterioration (PSD) review of new natural gas-fired generation sites.

The calculations for gas-fired units are structured very much the same as for coal- and oil-fired sources. For simple cycle combustion turbines, the only source of sulfuric acid is the sulfur in the fuel. The EPA AP-42 emissions factor suggests a value of 2000 grains of sulfur per million cubic feet of natural gas as a default sulfur content value. This value is equivalent to approximately 3.5 ppm of sulfur in the raw natural gas.

A methodology to estimate manufacture and release of sulfuric acid for simple cycle and combined cycle units is provided below.

Manufacture and Release for Simple Cycle Units

Given the current configuration of simple cycle units, any sulfuric acid *manufactured* is *released*; thus, the estimates of sulfuric acid are the same. This is because there is no equipment located following the simple cycle arrangement that removes sulfuric acid. Even though simple cycle units can be equipped with SCR, and the use of SCR with sulfur-containing fuels will manufacture SO₃, the exit gas temperature is too high to allow condensation of SO₃ or reaction with ammonia slip. Selective non-catalytic reduction is not applied to simple cycle or combined cycle combustion turbines; therefore, no estimation procedure is provided for that configuration.

Accordingly, the equations for formation of sulfuric acid from natural gas (NG) combustion are:

$$EM_{SC} = K \bullet F1 \bullet E2_{NG} \quad \text{Eq. 6-1}$$

where,

EM_{SC} = total H₂SO₄ *manufactured* from combustion, lbs/yr

K = Molecular weight and units conversion constant

$$= 98.07 / 64.04 \bullet 2000 = 3,063$$

98.07 = Molecular weight of H₂SO₄

64.04 = Molecular weight of SO₂

2,000 = Conversion from tons per year to pounds per year.

F1 = Fuel Impact Factor for NG

E_{2NG} = Sulfur dioxide (SO₂) emissions either: (1) recorded by a continuous emissions monitor, tons/yr, or (2) calculated from fuel burn data, tons/yr.

SO₂ emissions can be obtained through a calculation using the heat input of natural gas.

$$E_{2NG} = K_b \bullet B_{NG} \bullet S \quad \text{Eq. 6-2}$$

where,

E_{2NG} = Total SO₂ production from NG combustion, tons/yr

K_b = Molecular weight and units conversion constant = 0.0001359

B_{NG} = Burn of NG in Tbtu/yr

S = Sulfur content of natural gas, in grains per million standard cubic feet (Mscf), typically 2000 gr/10⁶ scf per EPA AP-42.

The derivation of constant K_b is presented in Text Box D.

Text Box D: Derivation of Molecular Weight and Units Conversion Constant, K_b

K_b is determined from the following equation.

$(K_b \bullet B_{NG} \bullet S) = \text{tons SO}_2 \text{ per yr} =$

B_{NG} TBtu	S gr S	1 scf nat gas	10 ¹² Btu	lb S	1 ton S	1 ton mol S	1 ton mole SO ₂	64 tons SO ₂
Year	10 ⁶ scf nat gas	1050 Btu	TBtu	7000 gr S	2000 lbs S	32 tons S	1 ton mol S	1 ton mole SO ₂

Grouping terms,

$= (B_{NG} \bullet S) \bullet 64 / (1050 \bullet 32 \bullet 14) = (B_{NG} \bullet S) \bullet 0.0001359$

Therefore, the value of K_b is equal to 0.0001359 tons SO₂/(TBtu • grains S/million SCF NG).

The SO₂ emissions can also be calculated from the volume of natural gas burned:

$$E_{2NG} = K_{NG} \bullet N1 \bullet S \quad \text{Eq. 6-3}$$

where,

E_{2NG} = total SO₂ production from NG combustion, tons/yr

K_{NG} = Molecular weight and units conversion constant = $1.427 \bullet 10^{-7}$

$N1$ = NG burn in million standard cubic feet (Mscf) per year

S = NG sulfur content in grains per million standard cubic feet; use EPA's value of 2000 gr/10⁶ scf as default

The derivation of constant K_{NG} is presented in Text Box E.

Text Box E: Derivation of Molecular Weight and Units Conversion Constant, K_{NG}

$(K_{NG} \bullet N1 \bullet S) = \text{tons SO}_2 \text{ per yr} =$

N1 10 ⁶ scf	S gr S	lb S	1 ton S	1 ton mol S	1 ton mole SO ₂	64 tons SO ₂
Year	10 ⁶ scf nat gas	7000 gr S	2000 lbs S	32 tons S	1 ton mol S	1 ton mole SO ₂

Grouping terms,

$(N1 \bullet S) \bullet 64 / (7000 \bullet 2000 \bullet 32) = (N1 \bullet S) \bullet 1.427 \bullet 10^{-7}$

Therefore, the value of K_{NG} is equal to $1.427 \bullet 10^{-7}$ tons SO₂/(grains S)

Table 6-1 presents the F1 factors for simple cycle units as a function of stack temperature, as sulfuric acid vapor is related to the temperature of the exhaust. As simple cycle combustion turbines (CT) exhaust is usually around 1000°F, and TRI rules require the reporting of sulfuric acid (not of SO₃), the amount manufactured and released depends on stack temperature. Table 6-1 combines the temperature-based SO₃ to H₂SO₄ conversion with the SO₂ to SO₃ conversion to give the Fuel Impact Factor, F1.

Table 6-1

Combined Cycle Units

Sulfuric Acid Manufactured

For combined cycle units, sources of *manufacture* of sulfuric acid are combustion, oxidation of SO₂ across catalyst used for NO_x control and recently, oxidation of SO₂ across catalyst used for CO control.

For combustion, the manufacture of sulfuric acid for combined-cycle units is described by Equation 6-4.

$$EM_{CCcom} = K \bullet F1 \bullet E2_{NG} \quad \text{Eq. 6-4}$$

where,

EM_{CCcom} = Total H₂SO₄ *manufactured* from combustion, lbs/yr

K = Molecular weight and units conversion constant

$$= 98.07/64.04 \bullet 2000 = 3,063$$

98.07 = Molecular weight of H₂SO₄;

64.04 = Molecular weight of SO₂;

2,000 = Conversion from tons per year to pounds per year.

F1 = Fuel Impact Factor for NG (See Table 4-1)

$E2_{NG}$ = Sulfur dioxide (SO₂) emissions either: (1) recorded by a continuous emissions monitor, tons/yr, or (2) calculated from fuel burn data, tons/yr.

Recently, it has been shown that CO catalysts in combined cycle units can oxidize SO₂ to SO₃ in a manner similar to SCRs. Equation 6-5 describes the manufacture of sulfuric acid across the CO catalyst. For the case of combined cycle combustion turbines, the CO catalyst SO₂ oxidation rate (S3) will be approximately 0.1. This value is an estimate based on data from a prominent catalyst vendor. A more accurate value can be obtained from field measurements of SO₂ oxidation, or from the vendor's specification of the CO catalyst.

$$EM_{cc_co} = K \bullet S3 \bullet f_{COops} \bullet E2 \quad \text{Eq. 6-5}$$

where,

EM_{cc_co} = Total H₂SO₄ manufactured from the CO catalyst, lbs per year

K = Molecular weight and units conversion constant

$$= 98.07/64.04 \bullet 2000 = 3,063$$

98.07 = Molecular weight of H₂SO₄

64.04 = Molecular weight of SO₂

2000 = Conversion from tons per year to pounds per year

- S3 = CO catalyst SO₂ oxidation rate (specified as a decimal, typically from 0.1-0.6)
- f_{COops} = Operating factor of CO catalyst system, or the fraction of fuel burn when the flue gas is directed through the CO catalyst. This value should reflect the fraction of hours that the CO catalyst processed flue gas. This value will be site-specific but can be approximated as 0.8 for year-round peaking operation, 0.98 for year-round base-loaded operation, or 0.43 for seasonal operation.
- E2 = SO₂ produced, tons per year

Equation 6-6 describes the manufacture of sulfuric acid in an SCR. The amount of sulfuric acid manufactured due to SO₂ oxidation across the CO catalyst (EM_{CC_CO}) must be subtracted from the total amount of SO₂ produced (E2), because the CO catalyst will reduce the amount available for conversion by the SCR catalyst. For the case of combined cycle combustion turbines, the SCR catalyst SO₂ oxidation rate (S2) will be approximately 0.03. A more precise value can be obtained from either field test reports of SO₂ oxidation, or from the vendor's specification of the SCR catalyst or process. The Technology Impact Factor for SCR, F_{3SCR}, will be 1.0.

$$EM_{CCSCR} = [(K \bullet E2) - EM_{CC_CO}] \bullet f_{sops} \bullet S2 \bullet F_{3SCR} \quad \text{Eq. 6-6}$$

where,

- EM_{CCSCR} = Total H₂SO₄ manufactured from SCR, lbs per year
- K = Molecular weight and units conversion constant
 = 98.07/64.04 • 2000 = 3,063
 98.07 = Molecular weight of H₂SO₄;
 64.04 = Molecular weight of SO₂;
 2,000 = Conversion from tons per year to pounds per year
- E2 = SO₂ produced, tons per year
- EM_{CC_CO} = Total H₂SO₄ manufactured from the CO catalyst, lbs per year
- S2 = SCR catalyst SO₂ oxidation rate (specified as a decimal, typically from 0.001- 0.03)
- f_{sops} = Operating factor of SCR system, or the fraction of coal burn when the flue gas is directed through the SCR, whether NH₃ reagent is injected to derive NO_x reduction or not. This value should reflect the hours the SCR reactor processed flue gas, which will be site-specific but can be approximated by generally 0.8 for year-round peaking operation, 0.98 for year-round base-loaded operation, or 0.43 for seasonal operation
- F_{3SCR} = Technology Impact Factor, for SCR (equal to 1.0, refer to Table 4-2)

The total sulfuric acid *manufacture* (TSAM) for a combined cycle unit is estimated using the equation below:

$$\text{TSAM}_{\text{CC}} = \text{EM}_{\text{CCcom}} + \text{EM}_{\text{CC_CO}} + \text{EM}_{\text{CCSCR}} \quad \text{Eq. 6-7}$$

Sulfuric Acid Released

The sulfuric acid released by all sources in combined cycle units is estimated as shown in Equation 6-8. This equation takes into account the reducing effect of ammonia slip from the SCR equipment in a similar method as described in Section 4:

$$\text{TSAR}_{\text{CC}} = [\text{TSAM}_{\text{CC}} - (\text{K}_s \bullet \text{B} \bullet \text{f}_{\text{sreagent}} \bullet \text{S}_{\text{NH3}})] \bullet \text{F2}_{\text{cc}} \quad \text{Eq. 6-8}$$

where,

- TSAR_{CC} = Total H₂SO₄ released, lbs per year
- TSAM_{CC} = Total H₂SO₄ manufactured from all sources, lbs per year
- K_s = Conversion factor = 3,799 (see Text Box B)
- B = Fuel burn in Tbtu/yr
- f_{sreagent} = Fraction of SCR operation with reagent injection, when residual NH₃ is produced that will remove SO₃.
- S_{NH3} = NH₃ slip from SCR, ppmv at 6% O₂, wet (averages 0.75 ppmv over catalyst guarantee period. Actual NH₃ slip data should be used if available)
- F2_{CC} = Technology Impact Factor for the combined cycle heat exchanger, equal to a value of 0.5.

Examples 9 and 10 of Appendix A illustrates a gas-fired combined cycle plant calculation.

A

EXAMPLE CALCULATIONS

Example 1: Conventional Coal-Fired Boiler with an ESP

A 500 MW pulverized coal-fired (PC) boiler, equipped with a cold-side electrostatic precipitator, burns an Eastern bituminous coal. The coal used in the reporting year is 1,126,938 tons with a weighted average sulfur concentration of 2.0% and a heating value of 12,000 Btu/lb.

Solution

Manufactured

$$E2 = K1 \bullet K2 \bullet C1 \bullet S1$$

$$E2 = 0.02 \bullet 0.95 \bullet 1,126,938 \bullet 2.0 = 42,824 \text{ tons SO}_2/\text{yr}$$

$$EM_{\text{Comb}} = K \bullet F1 \bullet E2$$

$$F1_{\text{eastbit}} = 1.1163\text{E-}6 \bullet \text{SO}_2 + 0.0064876$$

$$\text{SO}_2 = S1 \bullet \frac{K_{F1}}{HV} = 2.0 \bullet \frac{10,003,602}{12,000} = 1667 \text{ ppm}$$

$$F1_{\text{eastbit}} = 1.1163\text{E-}6 \bullet + 0.0064876 = 0.0083$$

$$EM_{\text{Comb}} = 3063 \bullet 0.0083 \bullet 42,824 = 1,088,710 \text{ lbs H}_2\text{SO}_4/\text{yr}$$

The 25,000 lbs/yr threshold has been exceeded; therefore, a release estimate must be made and the result reported on Form R.

Released

$$\text{TSAR} = EM_{\text{Comb}} \bullet F2_{\text{APH}} \bullet F2_{\text{ESP}}$$

$$\text{TSAR} = 1,088,710 \bullet 0.50 \bullet 0.63 = 342,944 \text{ lbs H}_2\text{SO}_4/\text{yr}$$

Example 2: SCR Added to Example 1

A 500 MW PC boiler, equipped with a cold-side electrostatic precipitator, burns an Eastern bituminous coal. The plant is equipped with an SCR process that operates during the ozone season only, so that 0.43 of the coal burn occurred with the SCR operating. The remaining time that the SCR is not in service the flue gas is bypassed around the SCR. The SCR catalyst SO₂ oxidation rate specified in the design is 0.75%, and the ammonia slip is estimated to be 0.75 ppmv. The coal used in the reporting year is 1,126,938 tons with a weighted average sulfur concentration of 2.0% and a heating value of 12,000 Btu/lb.

Solution

Manufactured

$$E2 = K1 \bullet K2 \bullet C1 \bullet S1$$

$$E2 = 0.02 \bullet 0.95 \bullet 1,126,938 \bullet 2.0 = 42,824 \text{ tons SO}_2/\text{yr}$$

Combustion

$$EM_{\text{comb}} = K \bullet F1 \bullet E2$$

$$F1_{\text{eastbit}} = 1.1163\text{E-}6 \bullet \text{SO}_2 + 0.0064877$$

$$\text{SO}_2 = S1 \bullet \frac{K_{F1}}{HV} = 2.0 \bullet \frac{10,003,602}{12,000} = 1667 \text{ ppm}$$

$$F1_{\text{eastbit}} = 1.1163\text{E-}6 \bullet + 0.0064877 = 0.0083$$

$$EM_{\text{Comb}} = 3063 \bullet 0.0083 \bullet 42,824 = 1,088,710 \text{ lbs H}_2\text{SO}_4/\text{yr}$$

SCR

$$EM_{\text{SCR}} = K \bullet S2 \bullet f_s \bullet E2$$

$$EM_{\text{SCR}} = 3063 \bullet 0.0075 \bullet 0.43 \bullet 42,824 = 423,023 \text{ lbs H}_2\text{SO}_4/\text{yr}$$

Total

$$\text{TSAM} = EM_{\text{comb}} + EM_{\text{SCR}}$$

$$\text{TSAM} = 1,088,710 + 423,023 \text{ lbs H}_2\text{SO}_4/\text{yr}$$

$$\text{TSAM} = 1,511,733 \text{ lbs H}_2\text{SO}_4/\text{yr}$$

The 25,000 lbs/yr threshold has been exceeded; therefore, a release estimate must be made and the result reported on Form R.

Released

Coal Burn

$$B = C1 \bullet HV \bullet K_B$$

$$B = 1,126,938 \text{ tons/yr} \bullet 2000 \text{ lbs/ton} \bullet 12,000 \text{ Btu/lb} \bullet 1 \text{ Tbtu}/10^{12} \text{ Btu}$$

$$B = 27.05 \text{ Tbtu/yr}$$

Ammonia Slip

$$NH3_{SCR} = K_s \bullet B \bullet f_{sreagent} \bullet S_{NH3}$$

$$NH3_{SCR} = 3799 \bullet 27.05 \bullet 0.43 \bullet 0.75 = 33,141 \text{ lbs } NH_3/\text{yr}$$

Total Releases

$$TSAR = [(EM_{Comb} + EM_{SCR/SNCR}) - (NH3_{SCR})] \bullet F2_{APH} \bullet F2_{ESP}$$

$$TSAR = [(1,088,710 + 423,023) - (33,141)] \bullet 0.50 \bullet 0.63$$

$$TSAR = 465,756 \text{ lbs } H_2SO_4/\text{yr}$$

Example 3: Alkali Injection Added to Example 2

A 500 MW PC boiler, equipped with a cold-side electrostatic precipitator, burns an Eastern bituminous coal. The plant is equipped with an SCR process that operates during the ozone season only, so that 0.43 of the coal burn occurred with the SCR operating. The remaining time that the SCR is not in service the flue gas is bypassed around the SCR. The SCR catalyst SO₂ oxidation rate specified in the design is 0.75%, and the ammonia slip is estimated to be 0.75 ppmv.

The plant employs injection of alkali material (e.g., lime, sodium bicarbonate, sodium bisulfate, etc.) to control SO₃ emissions at the stack. The plant operator has conducted a series of field tests to determine the amount of alkali material that must be injected to limit flue gas SO₃ concentration at the stack. The test contractor has issued a report defining the amount of alkali that should be added to limit the stack SO₃ to 5 ppm, as measured in the flue gas at 6.6% O₂, and 8.8% moisture. The alkali injection system will be operated throughout the entire year, so that no more than 5 ppm of SO₃ at the stated conditions of excess O₂ and moisture exist in the stack.

The coal burn rate in the reporting year is 1,126,938 tons, with a weighted average sulfur concentration of 2.0%, and a heating value of 12,000 Btu/lb.

The calculation of manufactured sulfuric acid is the same as Example 1, and is repeated here:

Solution

Manufactured

$$E2 = K1 \bullet K2 \bullet C1 \bullet S1$$

$$E2 = 0.02 \bullet 0.95 \bullet 1,126,938 \bullet 2.0 = 42,824 \text{ tons SO}_2/\text{yr}$$

Combustion

$$EM_{\text{comb}} = K \bullet F1 \bullet E2$$

$$F1_{\text{eastbit}} = 1.1163\text{E-}6 \bullet \text{SO}_2 + 0.0064877$$

$$\text{SO}_2 = S1 \bullet \frac{K_{F1}}{HV} = 2.0 \bullet \frac{10,003,602}{12,000} = 1667 \text{ ppm}$$

$$F1_{\text{eastbit}} = 1.1163\text{E-}6 \bullet + 0.0064877 = 0.0083$$

$$EM_{\text{Comb}} = 3063 \bullet 0.0083 \bullet 42,824 = 1,088,710 \text{ lbs H}_2\text{SO}_4/\text{yr}$$

SCR

$$EM_{\text{SCR}} = K \bullet S2 \bullet f_s \bullet E2$$

$$EM_{\text{SCR}} = 3063 \bullet 0.0075 \bullet 0.43 \bullet 42,824 = 423,023 \text{ lbs H}_2\text{SO}_4/\text{yr}$$

Total

$$\text{TSAM} = EM_{\text{comb}} + EM_{\text{SCR}}$$

$$\text{TSAM} = 1,088,710 + 423,023 \text{ lbs H}_2\text{SO}_4/\text{yr}$$

$$\text{TSAM} = 1,511,733 \text{ lbs H}_2\text{SO}_4/\text{yr}$$

The 25,000 lbs/yr threshold has been exceeded; therefore, a release estimate must be made and the result reported on Form R.

Released

The total sulfuric acid released is based on the maximum value allowed by alkali injection, as measured in the stack, and the volume flow rate of combustion products processed.

The concentration of SO₃ measured at the stack can be converted to a mass emission rate, as described by Equation 4-15

$$\text{ER}_{\text{ALKINJ}} = K_{\text{alkali}} \bullet B \bullet S_{\text{SO}_3} \bullet F_{\text{alkali}} \bullet F_{2x}$$

where,

$\text{ER}_{\text{ALKINJ}}$ = Total H₂SO₄ released from unit equipped with alkali injection, lbs per year

K_{alkali} = Constant, equal to 3,799, with units of lbs H₂SO₄/(Tbtu ppmv SO₃) (SO₃ measured at @ 6% O₂ and 8.1% H₂O)

B = 27.05 Tbtu/yr, for the specific case of Example 1

S_{SO_3} = SO₃ content as measured in the stack or particulate collector exit, corrected to a concentration basis of ppmv at 6% O₂, 8.1% moisture

F_{alkali} = fraction of operation with alkali addition to remove SO₃.

F_{2x} = 1 (as the SO₃ measurement is in the stack, there are no control technology components downstream of the measurement)

The conversion factor K_{alkali} is equal to 3,799 (see Text Box B). This constant is derived for the case where flue gas SO₃ is reported in terms of 6% oxygen and wet flue gas at 8.1% H₂O. However, the SO₃ concentration of 5 ppm in the stack is measured at slightly different conditions of excess O₂ and moisture (6.6% oxygen and 8.8% moisture and therefore, a new value of K_{alkali} must be calculated:

$$K_{\text{alkali}} (\text{O}_2, \text{H}_2\text{O}) = 3799 (6\% \text{ O}_2, 8.1\% \text{ H}_2\text{O}) \bullet [(100-8.1)/(100-\text{new H}_2\text{O})] \bullet [(20.9 - 6.0)/(20.9 - \text{new O}_2)]$$

$$K_{\text{alkali}} (\text{O}_2, \text{H}_2\text{O}) = 3799 (6\% \text{ O}_2, 8.1\% \text{ H}_2\text{O}) \bullet [(100-8.1)/(100-8.8)] \bullet [(20.9 - 6.0)/(20.9 - 6.6)]$$

$$K_{\text{alkali}} (6.6\%, 8.8\%) = 3799 \bullet [1.0077] \bullet [1.034]$$

$$K_{\text{alkali}} (6.6\%, 8.8\%) = 3958$$

Total sulfuric acid release is then calculated as follows:

$$\text{ER}_{\text{ALKINJ}} = [3,958] \bullet [27.05] \bullet [5.0] \bullet [1] \bullet [1]$$

$$ER_{ALKINJ} = 535,320 \text{ lbs/yr}$$

$$TSAR = ER_{ALKINJ}$$

$$TSAR = 535,320 \text{ lbs/yr}$$

Example 4: 500 MW PRB-fired Boiler with ESP, SCR

A 500 MW PC boiler, equipped with a cold-side electrostatic precipitator, burns a PRB coal. The plant is equipped with an SCR process that operates during the ozone season only, so that 0.43 of the coal burn occurred with the SCR operating. The SCR is bypassed when not in use. The SCR catalyst SO₂ oxidation rate specified in the design is 2%, and the ammonia slip is estimated to be 0.75 ppmv. The coal used in the reporting year is 1,384,552 tons with a weighted average sulfur concentration of 0.40% and a heating value of 8,500 Btu/lb.

Solution

Manufactured

$$E2 = K1 \bullet K2 \bullet C1 \bullet S1$$

$$E2 = 0.02 \bullet 0.875 \bullet 1,384,552 \bullet 0.40 = 9,692 \text{ tons SO}_2/\text{yr}$$

Combustion

$$EM_{\text{comb}} = K \bullet F1 \bullet E2$$

$$EM_{\text{comb}} = 3063 \bullet 0.0019 \bullet 9,692 = 56,405 \text{ lbs H}_2\text{SO}_4/\text{yr}$$

SCR

$$EM_{\text{SCR}} = K \bullet S2 \bullet f_s \bullet f_{\text{SCR}} \bullet E2$$

$$EM_{\text{SCR}} = 3063 \bullet 0.020 \bullet 0.43 \bullet 0.17 \bullet 9,692 = 43,402 \text{ lbs H}_2\text{SO}_4/\text{yr}$$

Total

$$\text{TSAM} = EM_{\text{comb}} + EM_{\text{SCR}}$$

$$\text{TSAM} = 56,404 + 43,402 \text{ lbs H}_2\text{SO}_4/\text{yr}$$

$$\text{TSAM} = 99,806 \text{ lbs H}_2\text{SO}_4/\text{yr}$$

The 25,000 lbs/yr threshold has been exceeded; therefore, a release estimate must be made and the result reported on Form R.

Released

Coal Burn

$$B = C1 \bullet HV \bullet K_B$$

$$B = 1,384,552 \text{ tons/yr} \bullet 2000 \text{ lbs/ton} \bullet 8,500 \text{ Btu/lb} \bullet 1 \text{ Tbtu}/10^{12} \text{ Btu}$$

$$B = 23.54 \text{ Tbtu/yr}$$

Ammonia Slip

$$\text{NH}_{3\text{SCR}} = K_s \bullet B \bullet f_{\text{sreagent}} \bullet S_{\text{NH}_3}$$

$$\text{NH}_{3\text{SCR}} = 3799 \bullet 23.54 \bullet 0.43 \bullet 0.75 = 28,841 \text{ lbs NH}_3/\text{yr}$$

Total Releases

$$\text{TSAR} = [(\text{EM}_{\text{Comb}} + \text{EM}_{\text{SCR/SNCR}}) - (\text{NH}_{3\text{SCR}})] \bullet \text{F}_{2\text{APH}} \bullet \text{F}_{2\text{ESP}}$$

$$\text{TSAR} = [(56,404 + 43,402) - (28,841)] \bullet 0.36 \bullet 0.72$$

$$\text{TSAR} = 18,394 \text{ lbs H}_2\text{SO}_4/\text{yr}$$

Example 5: FGC Added to Example 1

A 500 MW PC boiler, equipped with a cold-side electrostatic precipitator, burns an Eastern bituminous coal. The plant is equipped with a FGC process that injects both SO₃ and NH₃ upstream of the air preheater. The SO₃ is injected at 7 ppmv at 6% O₂ wet, and the ammonia at 3 ppmv also at 6% O₂ wet. The FGC system operates whenever the plant is on, except during startup and shutdown, with an operating factor estimated at 0.9. The coal used in the reporting year is 1,126,938 tons with a weighted average sulfur concentration of 2.0% and a heating value of 12,000 Btu/lb.

Solution

Manufactured

$$E2 = K1 \bullet K2 \bullet C1 \bullet S1$$

$$E2 = 0.02 \bullet 0.95 \bullet 1,126,938 \bullet 2.0 = 42,824 \text{ tons SO}_2/\text{yr}$$

Combustion

Total Releases

$$TSAR = [(EM_{Comb} + EM_{FGC}) - (NH3_{FGC})] \bullet F2_{APH} \bullet F2_{ESP}$$

$$TSAR = [(1,088,710 + 647,407) - (277,460)] \bullet 0.50 \bullet 0.63$$

$$TSAR = 459,477 \text{ lbs } H_2SO_4/\text{yr}$$

Example 6: SCR and FGC Added to Example 1

A 500 MW PC boiler, equipped with a cold-side electrostatic precipitator, burns an Eastern bituminous coal. The plant is equipped with an SCR process that operates during the ozone season only, so that 0.43 of the coal burn occurred with the SCR operating. The SCR is bypassed when not in operation. The SCR catalyst SO₂ oxidation rate specified in the design is 0.75%, and the ammonia slip is estimated to be 0.75 ppmv. The plant is also equipped with a FGC process that injects both SO₃ and NH₃ upstream of the air preheater. The SO₃ is injected at 7 ppmv at 6% O₂ wet, and the ammonia at 3 ppmv also at 6% O₂ wet. The FGC system operates whenever the plant is on, except during startup and shutdown, with an operating factor estimated at 0.9. The coal used in the reporting year is 1,126,938 tons with a weighted average sulfur concentration of 2.0% and a heating value of 12,000 Btu/lb.

Solution

Manufactured

Total (from previous examples)

$$TSAM = EM_{Comb} + EM_{SCR} + EM_{FGC}$$

$$TSAM = 1,088,710 + 423,023 + 647,407 \text{ lbs H}_2\text{SO}_4/\text{yr}$$

$$TSAM = 2,159,140 \text{ lbs H}_2\text{SO}_4/\text{yr}$$

The 25,000 lbs/yr threshold has been exceeded; therefore, a release estimate must be made and the result reported on Form R.

Released

Total Releases (from previous examples)

$$TSAR = [(EM_{Comb} + EM_{SCR} + EM_{FGC}) - (NH_{3SCR} + NH_{3FGC})] \bullet F_{2APH} \bullet F_{2ESP}$$

$$TSAR = [(1,088,710 + 423,023 + 647,407) - (33,141 + 277,460)] \bullet 0.50 \bullet 0.63$$

$$TSAR = 582,290 \text{ lbs H}_2\text{SO}_4/\text{yr}$$

Example 7: SCR and Downstream FGC Added to Example 1

A 500 MW PC boiler, equipped with a cold-side electrostatic precipitator, burns an Eastern bituminous coal. The plant is equipped with an SCR process that operates during the ozone season only, so that 0.43 of the coal burn occurred with the SCR operating. The SCR is bypassed when not operating. The SCR catalyst SO₂ oxidation rate specified in the design is 0.75%, and the ammonia slip is estimated to be 0.75 ppmv. The plant is also equipped with a FGC process that injects both SO₃ and NH₃ downstream of the air preheater. The SO₃ is injected at 7 ppmv at 6% O₂ wet, and the ammonia at 3 ppmv also at 6% O₂ wet. The FGC system operates whenever the plant is on, except during startup and shutdown, with an operating factor estimated at 0.9. The coal used in the reporting year is 1,126,938 tons with a weighted average sulfur concentration of 2.0% and a heating value of 12,000 Btu/lb.

Solution

Manufactured

Total (from previous examples)

$$TSAM = EM_{Comb} + EM_{SCR} + EM_{FGC}$$

$$TSAM = 1,088,710 + 423,023 + 647,407 \text{ lbs H}_2\text{SO}_4/\text{yr}$$

$$TSAM = 2,159,140 \text{ lbs H}_2\text{SO}_4/\text{yr}$$

The 25,000 lbs/yr threshold has been exceeded; therefore, a release estimate must be made and the result reported on Form R.

Released

Total Releases (from previous examples)

$$TSAR = \{[(EM_{Comb} + EM_{SCR}) - NH3_{SCR}] \bullet F2_{APH} + (EM_{FGC_afterAPH} - NH3_{FGC_afterAPH})\} \bullet F2_{ESP}$$

Check that subtotal from upstream sources is positive:

$$TSAR_{upstream} = [(1,088,710 + 423,023) - 33,141] = 1,478,592 > 0$$

$$TSAR = [(1,088,710 + 423,023) - 33,141] \bullet 0.50 + (647,407 - 277,460) \bullet 0.63$$

$$TSAR = 698,823 \text{ lbs H}_2\text{SO}_4/\text{yr}$$

Example 8: Coal-Fired Boiler with FGC, NG Startup Fuel, and Used Oil Co-Firing

A 500 MW PC boiler, equipped with a cold-side electrostatic precipitator, burns an Eastern bituminous coal as the main fuel. The plant is equipped with an SCR process that operates during the ozone season only, so that 0.43 of the coal burn occurred with the SCR operating. The SCR is bypassed when not in operation. The SCR catalyst SO₂ oxidation rate specified in the design is 0.75%, and the ammonia slip is estimated to be 0.75 ppmv. The plant is also equipped with a FGC process that injects both SO₃ and NH₃ upstream of the air preheater. The SO₃ is injected at 7 ppmv at 6% O₂ wet, and the ammonia at 3 ppmv also at 6% O₂ wet. The FGC system operates whenever the plant is on, except during startup and shutdown, with an operating factor estimated at 0.9.

The coal used in the reporting year is 1,126,938 tons with a weighted average sulfur concentration of 2.0% and a heating value of 12,000 Btu/lb.

Natural gas is used as a startup fuel, with 0.5 Tbtu per year. During startup, neither the SCR nor the FGC system is used. Used oil is also burned, with 483.2 tons burned (0.0185 Tbtu/yr) in the year. Since the used oil is burned when the unit is at full load, it is burned while the SCR and FGC are both operating. The used oil has a sulfur content of 0.1% from analysis.

Solution

Coal fuel calculations

Manufactured from coal

Total (from previous examples)

$$TSAM = EM_{Comb} + EM_{SCR} + EM_{FGC}$$

$$TSAM = 1,088,710 + 423,023 + 647,407 \text{ lbs H}_2\text{SO}_4/\text{yr}$$

$$TSAM = 2,159,140 \text{ lbs H}_2\text{SO}_4/\text{yr}$$

Released from coal

Total Releases (from previous examples)

Released

$$\text{TSAR} = \text{TSAR}_{\text{coal}} + \text{TSAR}_{\text{NG}} + \text{TSAR}_{\text{oil}}$$

$$\text{TSAR} = 582,290 + 1.31 + 95 \text{ lbs H}_2\text{SO}_4/\text{yr}$$

$$\text{TSAR} = 582,386 \text{ lbs H}_2\text{SO}_4/\text{yr}$$

Example 9: Natural Gas Combined Cycle Plant

A natural gas-fired combined-cycle unit uses 12.3 Tbtu/yr. of natural gas, with the standard sulfur content.

Solution

Manufactured

$$E_{2NG} = K_b \bullet B_{NG} \bullet S$$

$$E_{2NG} = 0.0001359 \bullet 12.3 \bullet 2000$$

$$E_{2NG} = 3.343 \text{ tons SO}_2/\text{yr} \square$$

Combustion

$$EM_{CC} = K \bullet F1 \bullet E_{2NG}$$

$$EM_{CC} = 3063 \bullet 0.0555 \bullet 3.343$$

$$EM_{CC} = 568 \text{ lbs H}_2\text{SO}_4/\text{yr}$$

Released

$$TSAR_{NG} = EM_{Comb} \bullet F2_{CC}$$

$$TSAR_{NG} = 568 \bullet 0.5$$

$$TSAR_{NG} = 284 \text{ lbs H}_2\text{SO}_4/\text{yr}$$

$F2_{CC} = 0.5$ because the low temperature of the back-end tubes of the HRSG act like an air heater.

Example 10: SCR and CO catalyst added to Example 9

A natural gas-fired combined-cycle unit uses 12.3 Tbtu/yr. of natural gas, with the standard sulfur content. The plant is equipped with an SCR process that operates continually (operating factor of 1.0). The SCR catalyst SO₂ oxidation rate specified in the design is 2.0%, and the ammonia slip is estimated to be 0.75 ppmv. The plant is also equipped with a CO catalyst, which also is in continuous operation, and has an estimated SO₂ oxidation rate of 10%.

Solution

Manufactured

$$E_{2NG} = K_b \bullet B_{NG} \bullet S$$

$$E_{2NG} = 0.0001359 \bullet 12.3 \bullet 2000$$

$$E_{2NG} = 3.343 \text{ tons SO}_2/\text{yr}$$

Combustion

$$EM_{CC} = K \bullet F_1 \bullet E_{2NG}$$

$$EM_{CC} = 3063 \bullet 0.0555 \bullet 3.343$$

$$EM_{CC} = 568 \text{ lbs H}_2\text{SO}_4/\text{yr}$$

CO Catalyst

$$EM_{CC_CO} = K \bullet S_3 \bullet f_{COops} \bullet E_2$$

$$EM_{CC_CO} = 3063 \bullet 0.1 \bullet 1.0 \bullet 3.343$$

$$EM_{CC_CO} = 1024 \text{ lbs H}_2\text{SO}_4/\text{yr}$$

SCR

$$EM_{CCSCR} = [(K \bullet E_2) - EM_{CC_CO}] \bullet f_{sops} \bullet S_2 \bullet F_{3SCR}$$

$$EM_{CCSCR} = [(3063 \bullet 3.343) - 1024] \bullet 1.0 \bullet 0.02 \bullet 1.0$$

$$EM_{CCSCR} = 184 \text{ lbs H}_2\text{SO}_4/\text{yr}$$

Total

$$TSAM_{CC} = EM_{Comb} + EM_{CC_CO} + EM_{SCR}$$

$$TSAM_{CC} = 568 + 1024 + 184$$

$$TSAM_{CC} = 1776 \text{ lbs H}_2\text{SO}_4/\text{yr}$$

Released

$$TSAR_{CC} = [TSAM - (K_s \bullet B \bullet f_{sreagent} \bullet S_{NH3})] \bullet F_{2cc}$$

$$TSAR_{CC} = [1776 - (3799 \bullet 12.3 \bullet 1.0 \bullet 0.75)] \bullet 0.5$$

$$TSAR_{CC} = -16,635 = 0 \text{ lbs H}_2\text{SO}_4/\text{yr}$$

The total releases are zero because the actual result is a negative value, indicating that the ammonia slip is greater than the sulfuric acid, thereby forming ABS, which is not reportable.

$F_{2CC} = 0.5$ because the low temperature of the back-end tubes of the HRSG act like an air heater.

B

CHRONOLOGY OF CHANGES TO THE EPRI SULFURIC ACID ESTIMATION MODEL

EPRI, 2018 (EPRI Report 3002012398)

Modification	Description
Stack correction for CEMs SO ₂ measurements	Added equation using wall affects factor (WAF) for CEMs measurements in conjunction with Method 2H.
Total Sulfuric Acid Release Methodology (TSAR)	Changed application location of F _{2Hotside_ESP} and F _{2Mag-Ox} such that they apply only to EM _{COMB} .
Partial-Year SCR/SNCR	Added methodology to calculate the Total Sulfuric Acid Release if injection for SCR/SNCR is partial-year.

EPRI, 2012 (EPRI Report 1023790)

Modification	Description
SCR Factor (F _{3SCR})	Changes made to Table 4-2 to clarify proper use of the F _{3SCR} factor.
Alkali Injection	<p>Changed description of F_{alkali} such that it is fraction of coal burn instead of fraction of operating year, to be consistent with other operating factors</p> <p>Added alternate approach for calculating releases with alkali injection to be used if the utility does not have measured data. F_{3ALKINJ} factor is introduced.</p>
Total Sulfuric Acid Release Methodology (TSAR)	Reorganized release equations such that sources are summed upstream of the APH and ammonia from SCR/SNCR is applied to reduce releases based on ABS formation, then the F ₂ factor for the APH is applied. Then, any downstream source of SO ₃ or ammonia from downstream FGC is added, followed by application of all remaining F ₂ factors.
FGC Factor (F _{3FGC})	Corrected the F _{3FGC} factor. The F _{3FGC} factor was introduced in the 2001 version of the report, but as actual data has become available to update the F ₂ factors, the F _{3FGC} factor has become outdated. F _{3FGC} will now account only for alkalinity in PRB coal, and be applied directly to the manufacture equation.

EPRI, 2012 (EPRI Report 1023790), continued

Combined Cycle	Introduced a potential third source of sulfuric acid manufacture and release from oxidation across CO catalysts.
Technology Factors (F2)	<p>Added Wet ESP, all fuels: 0.1.</p> <p>Changed FGD, venturi, all coals from 0.65 to 0.73 (2 new data points).</p> <p>Updated and corrected Figure 4-4 to reflect two new data points, change the shaded area to reflect the proper data range, and deleted an inaccurate PRB/lignite data point</p> <p>Changed the F2 factor in Table 4-6 for Mg-Ox into furnace from 0.5 to 0.25 to rectify an error introduced in the 2004 version of the report.</p>
Examples	Updated examples to account for new release equation methodology.

EPRI, 2010a (EPRI Report 1020636)

Modification	Description
Fuel Impact Factor (F1)	<p>Combined low and high-sulfur eastern bituminous coals into a single category with a linear curve fit. F1 factor based on fuel SO₂ content calculated from fuel sulfur content:</p> $F1_{\text{ebit}} = 1.1163\text{E-}6 \bullet \text{SO}_2 + 0.0065$ <p>Changed the following F1 factors based on additional data:</p> <p>Subbit/PRB – changed from 0.0018 to 0.0019</p> <p>Lignite – changed from 0.0048 to 0.0044</p>
Technology Factors (F2)	<p>Changed factors for APH and ESP due to addition and re-evaluation of data:</p> <p>APH, low-sulfur east. bit. – changed from 0.49 to 0.50</p> <p>APH, PRB – changed from 0.56 to 0.36</p> <p>ESP, low-sulfur east. bit – changed from 0.49 to 0.63</p> <p>ESP, PRB – changed from 0.73 to 0.72</p>

EPRI, 2010a (EPRI Report 1020636) (continued)

Alkali Injection	Added a procedure to determine total releases from partial year injection. Incorporated correction to alkali injection conversion factor, K_{alkali} .
Report Organization	Moved F2 Factors from Section 3 to Section 4.
Examples	Updated examples to account for new F1 and F2 factors.

EPRI, 2008 (EPRI Report 1016384)

Modification	Description
Alkali Injection	Added a procedure to estimate a stack release using a measured or specified stack gas SO_3 concentration, to support estimates on units with alkali injection. Errata page published to correct error in alkali injection conversion factor, K_{alkali} .
Combustion Turbines	Clarified procedures for estimating emissions from simple and combined cycle CTs.
Blended Coals	New method calculates SO_3 manufacture by calculating the SO_3 emission rate separately for each of the component coals, and proportioning the contribution of SO_3 from each. The prior method assumed the SO_3 production was the same as that of the major coal component.
Examples	Provided new example calculations for alkali injection and blended coal.

EPRI, 2007 (Report 1014773) changes from Harrison, 2005

Modification	Description
Formatting	Adapted Southern Company paper (Harrison, 2005) to EPRI format.
Fuel (F1) Factors	Changed the following F1 factors based on additional data: Low S E. Bit, Dry Boiler – from 0.0080 to 0.0082 Subbit. (including PRB), Dry Boiler – from 0.0014 to 0.0018 Subbit. (including PRB), Cyclone – from 0.003 to 0.0018

EPRI, 2007 (Report 1014773) changes from Harrison, 2005 (continued)

Technology (F2) Factors	Added new F2 Factors: Air Preheater, PRB fuel - 0.56 Cold-side ESP, PRB fuel – 0.73
SCR	Added a Technology Impact Factor for SCR, $F3_{SCR}$.

The Electric Power Research Institute, Inc. (EPRI, www.epri.com) conducts research and development relating to the generation, delivery and use of electricity for the benefit of the public. An independent, nonprofit organization, EPRI brings together its scientists and engineers as well as experts from academia and industry to help address challenges in electricity, including reliability, efficiency, affordability, health, safety and the environment. EPRI members represent 90% of the electric utility revenue in the United States with international participation in 35 countries. EPRI's principal offices and laboratories are located in Palo Alto, Calif.; Charlotte, N.C.; Knoxville, Tenn.; and Lenox, Mass.

Sulfuric Acid Mist Emissions Calculations at Coal Creek Station Due to Selective Catalytic Reduction using EPRI Guidance

GRE Coal Creek Station 2019 BART Review

Sulfuric Acid Mist Generation from SCR Operation

Basis EPRI publication 300201298: "Estimating Total Sulfuric Acid Emissions from Stationary Power Plants, 2018 Update"

The EPRI document describes an emissions estimation procedure for the manufacture and release of sulfuric acid from formation within the boiler and the SCR, and the effects of flue gas conditioning (FGC), alkali injection, and removal by downstream equipment such as air preheaters (APH), electrostatic precipitators (ESPs) and flue gas desulfurization (FGD) equipment.

This analysis only includes formation of sulfuric acid from the SCR, the effects of ammonia slip produced by the SCR, and removal by downstream pollution control equipment. Sulfuric acid manufactured by the boiler is not included in the calculations.

Sulfuric acid manufactured from SCR is estimated using the following equation.

$$\text{Eq. 4-7: } \text{EMSCR} = K \cdot S2 \cdot \text{fsops} \cdot E2 \cdot F3\text{SCR}$$

where,

EMSCR = Total H_2SO_4 manufactured from SCR, lbs per year

K = Molecular weight and units conversion constant = $98.07 / 64.04 \cdot 2000 = 3,063$

98.07 = Molecular weight of H_2SO_4

64.04 = Molecular weight of SO_2

2000 = Conversion from tons per year to pounds per year.

S2 = SCR catalyst SO_2 oxidation rate (specified as a fraction, typically from 0.001- 0.03),

Catalyst Manufacturer's suggested oxidation rate for the proposed catalyst is 0.05.

fsops = Operating factor of SCR system, or the fraction of coal burn when the flue gas is directed through the SCR, whether NH_3 reagent is injected to derive NO_x reduction or not. This value should reflect the hours the SCR reactor processed flue gas, which will be site-specific but can be approximated by generally 0.8 for year-round peaking operation, 0.98 for year-round base- loaded operation, or 0.43 for seasonal operation.

E2 = SO_2 produced, tons per year

F3SCR = Technology Impact Factor, for SCR. Table 4-2 recommends a factor of 1 for all coals except PRB.

K	S2	fsops	E2	F3SCR	EMSCR			
			tons/year		lb/hour	lb/year	ton/year	lb H_2SO_4 / ton SO_2
3,063	0.05	0.98	40,500	1	796	6,078,524	3,039	150

The Total Sulfuric Acid Release accounts for sulfuric acid manufactured from the SCR, the amount removed by ammonia slip, and the amount captured by downstream emission control equipment. Ammonia slip from the SCR can combine with some or all of the sulfuric acid generated to reduce the amount released.

Total Sulfuric Acid Release (TSAR) is described by the following equation:

$$\text{Eq. 4-11 TSAR} = (((\text{EMComb} \cdot \text{F2Hotside_ESP} \cdot \text{F2Mag_ox}) + \text{EMSCR} + \text{EMFGC_beforeAPH}) - (\text{NH3SCR} + \text{NH3FGC_beforeAPH})) \cdot \text{F2APH} + (\text{EMFGC_afterAPH} - \text{NH3FGC_afterAPH}) \cdot \text{F2x}$$

where,

TSAR =	Total Sulfuric Acid Release, lbs per year
EMComb =	Total sulfuric acid manufactured from combustion, lbs per year. Only H ₂ SO ₄ manufactured by the SCR is addressed in this analysis.
F2Hotside_ESP =	Technology Impact Factor for hot-side ESP. Only H ₂ SO ₄ manufactured by the SCR is addressed in this analysis so this factor is not applicable.
F2Mag-Ox =	Technology Impact Factor for magnesium oxide addition in fuel or furnace. Only H ₂ SO ₄ manufactured by the SCR is addressed in this analysis so this factor is not applicable.
EMSCR =	Total sulfuric acid manufactured from SCR, lbs per year. See equation 4-7 above.
EMFGC_beforeAPH =	Total sulfuric acid manufactured from FGC upstream of the air preheater (APH). Not Applicable.
NH3SCR =	Total equivalent ammonia slip produced from SCR/SNCR, lbs per year. See equation 4-13 below.
NH3FGC_beforeAPH =	Total equivalent ammonia produced from FGC upstream of the APH, lbs per year.
F2APH =	Technology Impact Factor for APH, applied only if subtotal for releases upstream of the APH is non-negative = 0.5, average measurement for air preheater, Table 4-3.
EMFGC_afterAPH =	Total sulfuric acid manufactured from FGC downstream of the APH. Not Applicable.
NH3FGC_afterAPH =	Total equivalent ammonia produced from FGC downstream of the APH, lbs per year
F2x =	Technology Impact Factors for processes downstream of the APH, all that apply Cold Side ESP F2 Factor 0.65 equivalent to 35% eff Spray Tower FGD F2 Factor 0.45 equivalent to 55% eff Control Equip F2 Factor F2 _x 0.29 equivalent to 71% eff

RE: Regional Haze Four-factor Analysis for SO₂ and NO_x Emissions at Coal Creek Station Units 1 and 2

Dear Mr. Semerad:

This letter and attachment serve to respond to the North Dakota Department of Environmental Quality's (NDDEQ) May 2, 2018 request for Great River Energy (GRE) to prepare a "four factors" analysis (herein termed a four-factor analysis) of SO₂ and NO_x emissions control measures for Coal Creek Station Units 1 and 2.¹ The NDDEQ had requested that this analysis be submitted by January 31, 2019. In follow-up conversations with NDDEQ staff during 2018 and 2019, GRE agreed to focus first on completing an updated best available retrofit technology (BART) analysis of NO_x emissions for the phase 1 State Implementation Plan (SIP). The updated NO_x BART analysis was submitted to the NDDEQ on September 12, 2019. We understand that submission of this SO₂ four-factor analysis before the end of 2019 is timely for the NDDEQ's preparations on the phase 2 SIP (RHR2), due to the U.S. Environmental Protection Agency (EPA) by July 31, 2021.

Under RHR2, the NDDEQ four-factor analysis request is specific to SO₂ and NO_x emissions because "sulfate and nitrates continue to be the largest contributors to visibility impairment" at North Dakota's Class I areas. For informational purposes, actual annual SO₂ emissions in the last decade from GRE's electric generating units in North Dakota – Coal Creek Station, Stanton Station, and Spiritwood Station – have decreased from nearly 31,000 tons in 2009 to less than 6,900 tons in 2018, representing a 78 percent reduction. In this same time frame, actual annual NO_x emissions have decreased 44 percent from nearly 13,000 tons in 2009 to 7,300 tons in 2018.

¹ May 2, 2018 letter from Terry O'Clair of the North Dakota Department of Health (now the North Dakota Department of Environmental Quality) to Mary Jo Roth of Great River Energy. Pursuant to a June 1, 2018 teleconference between GRE and NDDEQ staff, the NDDEQ confirmed that the four-factor analysis is to be completed only for the two electricity generating units, Unit 1 and Unit 2, which together constitute the vast majority of the actual SO₂ and NO_x emissions at Coal Creek Station. Other emissions units at Coal Creek Station are not subject to the four-factor analysis.

SO₂ Four-factor Analysis

The enclosed technical report (SO₂ four-factor report) provides a detailed analysis of SO₂ emissions control measures at Units 1 and 2. This report is based on and references EPA's final regional haze SIP guidance² issued on August 20, 2019 (2019 RH SIP Guidance), per verbal communication with NDDEQ staff, instead of earlier draft guidance issued in 2016 that was referenced in the May 2, 2018 NDDEQ letter.

The SO₂ four-factor report describes existing operations and SO₂ emissions performance at Units 1 and 2. As a result of GRE's work in recent years to better understand the opportunities and implications of reducing SO₂ emissions with its existing infrastructure (i.e., wet scrubber system, flue gas reheat technology, and dry stack design), GRE determined its baseline annualized SO₂ emissions performance level to be 626 lb/hr at each unit, which is equivalent to 0.104 lb/MMBtu at full load conditions.³ Setting this emissions rate for the baseline control scenario is consistent with the 2019 RH SIP Guidance. It is also notably less than the current 0.15 lb/MMBtu BART limit on a 30-day rolling average. The SO₂ performance level is consistent with operation of multiple emissions control measures in place, namely the wet scrubber system, DryFinishingTM technology, and flue gas reheat applications.

An assessment of additional SO₂ emissions control measures was conducted relative to this baseline control scenario. Upon review of potentially available control technologies, the two technically feasible measures that were further evaluated in the four-factor analysis are both intended to increase the amount of flue gas to the existing wet scrubbers by either: 1) replacing the current stack with a wet stack design, or 2) installing a natural gas-fired flue gas reheat system to maintain dry stack operating temperature. GRE estimates that the annual SO₂ emissions performance level from either of these measures is 0.080 lb/MMBtu compared to the baseline control scenario of 0.104 lb/MMBtu.

The costs of compliance for these two control measures have been determined with a screening-level engineering cost estimate. The cost effectiveness analysis of either control measure is summarized in the following table and is compared to the cost effectiveness threshold of \$4,630/ton represented in today's dollars. The cost of either control measure is significantly greater than this threshold. GRE believes the screening-level costs provided in Appendix A of this report are conservatively low and that a more detailed cost estimate is likely to increase the costs for installing and implementing either of the projects.

² US EPA, "Guidance on Regional Haze State Implementation Plans for the Second Implementation Period," August 20, 2019, EPA-457/B-19-003.

³ 626 lb/hr = 0.104 lb/MMBtu x 6,015 or 6,022 MMBtu/hr rated capacities for Unit 1 and 2 listed in the Title V operating permit.

SO ₂ Emissions Control Measure	Installed Capital Cost (\$)	Annualized Capital Cost (\$/yr)	Annual Operating Costs (\$/yr)	Total Annualized Costs (\$/yr)	Annual SO ₂ Emissions Reduction (tpy)	Pollution Control Cost Effectiveness (\$/ton)
New Wet Stack	\$38.8 million	\$3.2 million	\$0.8 million	\$4.0 million	550	7,200
Natural Gas Reheat System	\$14.5 million	\$1.2 million	\$2.2 million	\$3.4 million	550	6,200

Additionally, the observations of energy and environmental burden from installation of these measures (i.e., demolition and disposal of the existing stacks, natural gas combustion NO_x emissions from the flue gas reheat system) leads to the conclusion that these additional emissions control measures are not reasonably supported at Units 1 or 2.

In consultation with the NDDEQ, GRE proposes a federally enforceable SO₂ emissions rate limit of 626 lb/hr as an annualized average (365-boiler-operating-day rolling average) limit for each unit, with plant averaging between the two units. GRE proposes to implement operational practices summarized in Section 2.5 of the report in order to comply with the proposed SO₂ emissions rate limit, effective upon approval of a federally enforceable permit to construct (PTC) issued by the NDDEQ. This new performance level further reduces annual SO₂ emissions at each unit by an estimated 1,050 tpy in comparison to the BART limit.⁴

NO_x Four-factor Analysis

GRE submitted to the NDDEQ an updated NO_x BART report for Units 1 and 2 on September 12, 2019. This updated report follows the same evaluation steps as the SO₂ four-factor report summarized above with respect to the following two key elements:

- The annual NO_x emissions performance level is updated to reflect current and expected conditions, as was done for the SO₂ four-factor analysis, in order to appropriately evaluate the effectiveness of additional future control measures.
- The analysis of additional available NO_x emissions control measures follows the same four statutory factors (costs of compliance, energy and non-air environmental impacts, pollution control equipment in use at the source, and remaining useful life of the source) that are used in the SO₂ four-factor analysis, in addition to the visibility impacts analysis.

With respect to the first bullet, Unit 2 is currently operating at an annual NO_x emissions performance level of 0.13 lb/MMBtu. Unit 1 is scheduled to install the same LNC3+ NO_x control technology in the first half of 2020 and will therefore have equivalent NO_x performance. Using the same methodology as in the

⁴ Comparing the two SO₂ performance levels and applying the 87% annual capacity factor equals an emissions reduction of 1,054 tpy at each unit. (0.15 lb/MMBtu BART limit 30-day rolling average - 0.104 lb/MMBtu expected level 365-day rolling average) x (6,015 or 6,022 MMBtu/hr rated capacities for Unit 1 and 2) x (87% annual capacity factor), converted to tpy basis.

SO₂ four-factor report for full-load operation, the corresponding annualized baseline NO_x emissions level is 782 lb/hr for each unit.⁵

A thorough evaluation of potentially available control measures was completed in the updated BART analysis that resulted in two technologies, selective non-catalytic reduction (SNCR) and selective catalytic reduction (SCR), that were examined against the same four statutory factors as in the SO₂ report. Significant technical feasibility concerns were noted in the BART report of implementing either of these controls at Coal Creek Station, but both controls were conservatively carried forward into the more detailed, cost of compliance evaluation.

The costs of compliance for these two measures were determined in the BART report by third-party engineering firms. The cost effectiveness of either measure is summarized in the following table excerpted from the updated BART report and is compared to the same cost effectiveness threshold of \$4,630/ton as in the SO₂ four-factor report. The cost of either NO_x control measure is significantly greater than this threshold.

NO _x Emissions Control	Installed Capital Cost (\$)	Annualized Capital Cost (\$/yr)	Annual Operating Costs (\$/yr)	Total Annualized Costs (\$/yr)	Annual NO _x Emissions Reduction (tpy)	Pollution Control Cost Effectiveness (\$/ton)
SNCR	\$12.8 million	\$1.1 million	\$4.4 million	\$5.4 million	692	7,818
SCR	\$180 million	\$12.1 million	\$3.4 million	\$15.4 million	1,153	13,391

Additionally, the BART report describes other environmental impacts and implementation issues if SCR or SNCR were to be applied at Coal Creek Station, leading to the conclusion that these SNCR or SCR emissions control measures are not reasonably supported at Units 1 or 2.

In consultation with the NDDEQ for RHR2, GRE proposes a federally enforceable NO_x emissions rate limit of 782 lb/hr as an annualized average (365-boiler-operating-day rolling average) limit for each unit, with plant averaging between the two units. This is consistent with the updated NO_x BART report that establishes 0.13 lb/MMBtu as the baseline. GRE proposes to implement operational practices summarized in Section 2.1 of the updated BART report, specifically DryFining™ and LNC3+ technologies, in order to comply with the proposed NO_x mass emissions limit. The NO_x limit shall be effective after both approval of a federally enforceable PTC issued by the NDDEQ and startup of LNC3+ technology at Unit 1.

⁵ 782 lb/hr = 0.13 lb/MMBtu x 6015 or 6022 MMBtu/hr rated capacities for Unit 1 and 2 listed in the Title V operating permit.

1 Introduction

The Regional Haze Rule (RHR),¹ published on July 15, 2005 by the U.S. Environmental Protection Agency (EPA), defines regional haze as “visibility impairment that is caused by the emission of air pollutants from numerous sources located over a wide geographic area. Such sources include, but are not limited to, major and minor stationary sources, mobile sources, and area sources.” The RHR requires state regulatory agencies to submit a series of state implementation plans (SIPs) in ten-year increments to protect visibility in certain national parks and wilderness areas, known as mandatory federal Class I areas. The original state SIPs were due on December 17, 2007 and included milestones for establishing reasonable progress towards the visibility improvement goals, with the ultimate goal to achieve natural background visibility by 2064. The original SIP was informed by best available retrofit technology (BART) analyses that were completed on all subject-to-BART sources. The second RHR planning period requires development and submittal of updated state SIPs by July 31, 2021.

On May 2, 2018, the North Dakota Department of Environmental Quality (NDDEQ), formerly known as the North Dakota Department of Health, requested that Great River Energy (GRE) complete a “four factors” analysis (herein termed a four-factor analysis), for Coal Creek Station (CCS) Units 1 and 2 as part of the state’s regional haze reasonable progress.² The analysis considers the following four statutory factors:

1. The cost of compliance;
2. The time necessary to achieve compliance;
3. The energy and non-air quality environmental impact of compliance; and
4. The remaining useful life of any existing source subject to such requirements.

The NDDEQ’s May 2018 letter to GRE specified that the “... analysis should be prepared using the draft EPA guidance,” referring to a draft EPA regional haze SIP guidance document issued in July 2016.³ Since

¹ The EPA also refers to this regulation as the Clean Air Visibility Rule. The regional haze program requirements are promulgated at 40 CFR 51.308. The SIP requirements for this implementation period are specified in §51.308(f).

² May 2, 2018 letter from Terry O’Clair of NDDEQ to Mary Jo Roth of GRE. Pursuant to a June 1, 2018 teleconference between GRE and NDDEQ staff, the NDDEQ confirmed that the four-factor analysis is to be completed only for the two electricity generating units, Unit 1 and Unit 2, which together constitute the vast majority of the actual SO₂ and NO_x emissions at Coal Creek Station. Other emissions units at Coal Creek Station are not subject to the four-factor analysis.

³ US EPA, “Draft Guidance on Progress Tracking Metrics, Long-term Strategies, Reasonable Progress Goals and Other Requirements for Regional Haze State Implementation Plans for the Second Implementation Period,” July 2016, EPA-457/P-16-001.

then, EPA has issued final regional haze SIP guidance⁴ on August 20, 2019 (2019 RH SIP Guidance) that replaces the 2016 draft guidance. Pursuant to verbal communications with NDDEQ, the four-factor analysis is conducted in accordance with the four statutory factors described in the 2019 RH SIP Guidance.

This report describes the background and analysis for conducting a four-factor analysis for sulfur dioxide (SO₂) as applied to the review of emissions controls at GRE CCS.⁵ Coal Creek Station consists of two coal-fired electric generating units. Both boilers are tangentially-fired boilers manufactured by Combustion Engineering (CE, now a part of General Electric, or GE), and each unit produces about 605 megawatts (MW) of power on a gross basis. Coal Creek Station is a mine-mouth facility located near Underwood, North Dakota and burns lignite coal from the co-located Falkirk Mine.

For informational purposes, actual SO₂ emissions in the last decade from GRE's electric generating units (EGUs) located in North Dakota – Coal Creek Station, Stanton Station, and Spiritwood Station – have decreased from nearly 31,000 tons in 2009 to less than 6,900 tons in 2018, representing a 78 percent reduction in SO₂ emissions. The aggregated actual annual SO₂ emissions for the last 10 calendar years from GRE's North Dakota EGUs are illustrated in Figure 1-1. During this period:

- GRE commenced operation of its combined heat and power plant, Spiritwood Station, located on the east side of North Dakota. Given its best available emission controls (BACT), Spiritwood Station does not cause or contribute to regional haze at Class 1 areas based on a screening "Q/D" determination made by the North Dakota Department of Environmental Quality (NDDEQ).⁶
- GRE has permanently ceased operations of its 180 MW coal-fired power plant located just outside of Stanton (Stanton Station). Stanton Station's retirement results in an SO₂ actual emissions reduction of approximately 2,500 tons annually.
- GRE implemented DryFining™ and flue gas reheat technology at CCS, as described in more detail below, which are novel multi-pollutant emission controls that do not exist anywhere else in the world.

⁴ US EPA, "Guidance on Regional Haze State Implementation Plans for the Second Implementation Period," August 20, 2019, EPA-457/B-19-003.

⁵ As described in the cover letter, the regional haze four-factor analysis for NO_x emissions was provided in separate correspondence and is effectively the updated BART report dated September 12, 2019.

⁶ Information on Spiritwood Station's screening analysis provided by NDDEQ staff during teleconference between GRE and NDDEQ staff on June 1, 2018.

Figure 1-1: Annual SO₂ Emissions from GRE Electric Generating Units in North Dakota

2 Existing Operations and SO₂ Emissions Performance

In 2007, GRE submitted its BART analysis that evaluated SO₂ control strategies, in addition to particulate matter (PM), and oxides of nitrogen (NO_x).⁷ For SO₂, this BART analysis determined that EPA's presumptive emissions level of 0.15 pounds per million British thermal units (lb/MMBtu), as a 30-day rolling average, appropriately met BART requirements. GRE proceeded with installation and operation of DryFinishing™ in conjunction with additional work on scrubber modifications and conversion to a "wet stack" design in order to meet the presumptive emissions level.^{8,9}

DryFinishing™ technology was installed and became operational on January 1, 2010 as further described in Section 2.1. However, as GRE was making preparations to convert its existing stacks to a wet stack design pursuant to Electric Power Research Institute (EPRI) guidance currently available at that time (1996 EPRI Guide),¹⁰ EPRI issued new guidance (2012 EPRI Guide) based on additional day-to-day operational observations and information gathered from wet stacks.¹¹ Specifically, EPRI lowered the allowable exit velocity for a wet stack, which caused the GRE design stack velocity to be higher than the new specifications. Thus, GRE's wet stack conversion project was discontinued. See Section 2.2 for additional details.

Subsequently, in 2017, GRE designed and implemented a novel stack flue gas reheat system, which increases the exhaust temperature in order to allow each unit to operate with a dry stack and with improved capture of the flue gas to the existing wet gas scrubber (i.e., reduced use of the scrubber bypass). See Section 2.3 for a description of this system.

GRE currently operates the DryFinishing™ system, the existing four-module wet flue gas desulfurization (FGD) scrubbers, and the newly installed novel reheat system in order to comply with the SO₂ presumptive BART limit, which became effective May 2017. Together, the DryFinishing™ technology and the novel reheat system are a unique emissions control design, requiring a site-specific evaluation for consideration of

⁷ GRE, "Coal Creek Station Units 1 and 2 Best Available Retrofit Technology Analysis," revised December 12, 2007.

⁸ DryFinishing™ is referred to in Section 5.2.1 of the GRE December 2007 BART Analysis Report as "coal drying." This pre-combustion emissions control project was later implemented and trademarked as DryFinishing™.

⁹ A "wet stack" is designed to exhaust saturated (i.e., 100% relative humidity) flue gas downstream from a wet flue gas desulfurization system without causing problems such as stack liquid discharge, plume downwash and icing, and corrosion/chemical attack. The Unit 1 and 2 stacks were originally designed as "dry stacks," meaning that the inner metallurgy and other physical characteristics of the stacks are not meant to carry a saturated exhaust stream.

¹⁰ EPRI, "Wet Stacks Design Guide," November 1996, EPRI Technical Report No. TR-107099.

¹¹ EPRI, "Revised Wet Stack Design Guide," December 2012, EPRI Technical Report No. TR-1026742.

further SO₂ emission reductions. In Section 3.3.4, GRE evaluates opportunities to optimize scrubber performance for all operating modes.

2.1 DryFining™ Technology

In collaboration with many project participants, including the Department of Energy (DOE), the Lignite Research Council (LRC), Lehigh University, and EPRI, among others, GRE developed, tested, and commercialized the DryFining™ technology. DryFining™ is a multi-pollutant control technology, and Coal Creek Station represents the first full-scale, commercial installation of this technology. In short, this technology reduces coal moisture to increase the heat content of Fort Union lignite, which has the highest moisture content of any coal in the US. The DryFining™ process is also designed to segregate dense material (pyritic sulfur) from the coal prior to combustion to support SO₂ reductions.

DryFining™ was fully operational on January 1, 2010 and has since demonstrated a heat input reduction of approximately 2 to 3 percent for the same level of output. This heat input reduction correspondingly decreased the amount of flue gas created by the combustion process, which in turn has allowed for an additional proportion of gas to be routed to the wet scrubber instead of bypassing the scrubber. The corresponding SO₂ emissions rate on a lb/MMBtu decreased upon operation of DryFining™. For illustrative purposes, Figure 2-1 summarizes the calendar-year SO₂ emissions on a lb/MMBtu basis prior to, and after implementation of, DryFining™ at Unit 1. Unit 2 has a similar SO₂ emissions reduction trend.

Figure 2-1: Unit 1 Annual SO₂ Emissions Prior to and After DryFining™

2.2 Wet Stack Conversion Efforts

Consistent with its 2007 SO₂ BART assessment and report, GRE also began implementation of its wet stack conversion project which, in conjunction with DryFining™, was intended to improve the amount of exhaust gas to the wet scrubber. The wet stack conversion project at both stacks was planned to occur over 3-year outage increments and would have been completed by 2017. However, during conversion to wet stack as mentioned, EPRI revised its wet stack guide, which caused the planned design velocities for Units 1 and 2 stacks to be higher than the new specification, potentially resulting in stack liquid discharge, also known as stack rainout. This section describes the history of GRE's wet stack conversion efforts as related to EPRI's design guide.

In 1996, EPRI issued a design guide for wet stacks.¹² The 1996 EPRI Guide was prepared in order to address problems that were being caused by the presence of liquid water in electric utility chimneys

¹² EPRI, "Wet Stacks Design Guide," November 1996, EPRI Technical Report No. TR-107099.

downstream of wet flue gas desulfurization systems. The liquid water originates from water droplets passing through wet scrubber mist eliminator systems and from water condensation in the chimney. Most of the liquid water accumulates on the chimney walls and can be captured by water collection systems in a properly designed "wet stack." In order for the wet stacks to function properly, the chimney design must limit flue gas velocities to less than the recommended values as identified by EPRI's wet stack design guidelines. If stack velocities are higher than the guidelines, water droplets have the potential to form in the gas/liquid interface at the stack wall. These droplets will then become entrained in the exhaust gas and carried out of the stack, which causes liquid discharge conditions. Additionally, the water droplets carried out the chimneys create an acidic precipitation and deposition of liquid droplets from the stack plume onto the surrounding area. This condition is generally called "stack rainout." Winter operations at CCS further complicate the issue due to downwash at the chimney exit and the potential for ice buildup.

Based on the 1996 EPRI Guide, GRE commissioned three technical studies to evaluate the potential for mitigating these adverse impacts:

1. In 2004, the CCS wet stack design included a dual liner with brick liner in the lower portion of the stack and alloy liner in the top portion of the stack. The velocities in the brick liner were expected to exceed the EPRI recommendation of 55 feet per second (fps) for approximately 70 lineal feet of the stack. The alloy velocities were limited to the EPRI recommendation of 70 fps.
2. In 2005, URS Corporation performed computational flow dynamic modeling of the CCS stacks to address flue gas downwash and icing potentials at the stack exit.
3. In 2006, Alden Research Laboratory, Inc. constructed a scale model of the CCS chimneys to evaluate wet stack operation and concluded that the velocities in the brick liner would be consistent with the 1996 EPRI Guide with modifications made to the liner.

Based on these three studies, GRE began to implement the wet stack conversion changes.

During the course of making these stack improvements, industry began to report that stack rainout events were occurring while operating in accordance with the 1996 EPRI Guide. In response to these industry observations, EPRI revised its wet stack design guide (2012 EPRI Guide).¹³ The new maximum gas velocity in the 2012 EPRI Guide was lowered to be approximately 45 fps for brick liners and approximately 55 fps for alloy liners.

At full load, CCS stack velocities average 65 to 70 fps in both units based on 40 CFR Part 75 stack monitoring, which has been verified by independent stack testing firms. Although conforming with the 1996 EPRI Guide, both CCS Unit 1 and 2 greatly exceeded the 2012 EPRI recommended maximum gas flow velocities for both the lower brick portion and upper alloy portion of the stacks. Calculated inner diameters needed to avoid stack rainout is 32 feet for the brick portion and 30 feet for the alloy portion of

¹³ EPRI, "Revised Wet Stack Design Guide," December 2012, EPRI Technical Report No. TR-1026742. EPRI notes that, "A limited number of units, although designed within the recommendation of the original Wet Stack Design Guide, experienced "stack liquid discharge" (SLD), or rainout, from the start. It was found that most of these units had been designed for the higher end of the recommended liner-gas velocity range..."

the stacks. The concrete shell of both Unit 1 and 2 stacks has exit inner diameters of 29 feet, making it impossible to expand liners inside the shell to a diameter large enough to achieve velocities consistent with the 2012 EPRI Guide. In summary, the current design of the stacks prevents their conversion to wet stacks, so a complete replacement of the two stacks would be necessary if the stack gas temperature were to be at saturated conditions.¹⁴

To confirm the 2012 EPRI values for maximum gas velocities, GRE conducted a test in 2013 to evaluate the impacts of closing the bypass damper as much as physically possible in order to route the boiler flue gas through the wet scrubbing systems. Only a portion of the stack liner upgrade had been completed at the time of the test. During the tests GRE observed the following conditions:

- Stack liquid discharge and rainout, confirming that 1996 EPRI Guide values were not protective.
- Scrubbing water break-through onto the mist eliminators at a lower flue gas velocity than predicted due to improper design.
- Actual stack velocity data that are higher than the predicted design.

In 2014, an additional test was completed in order to reflect a state of maximizing the flue gas to the wet scrubber. This test did not experience stack liquid discharge and rainout. However, it was determined that the scrubber bypass leakage was approximately 6 percent during the test. The plant was unable to completely close/blind the bypass, so some bypass flue gas leaked through to the scrubbed gas, effectively reheating it to maintain a dry stack condition.

Following these tests, GRE replaced the wet scrubber mist eliminators in order to minimize water carryover from the wet scrubbers. Nevertheless, water accumulation on chimney walls due to condensation could not be eliminated when GRE maximized the proportion of flue gas to the wet scrubber. Therefore, a different solution was needed.

The technical conclusions and subsequent testing results described above were driving factors to cease work on the wet stack conversion project, resulting in abandoned costs of approximately \$20 million. Instead, GRE designed and implemented a novel flue gas reheat system as described in Section 2.3 so that the stacks could operate in a dry (non-saturated) state to comply with the SO₂ BART limit of 0.15 lb/MMBtu.

2.3 Flue Gas Reheat Technology

To maintain dry stack conditions while increasing the proportion of flue gas to the wet scrubber, GRE designed and installed a novel flue gas reheat system in late spring and early summer of 2017. The design

¹⁴ Saturation conditions or saturation temperature refers to the stack temperature at which a wet stack occurs, thus creating potential for stack liquid discharge, rainout, and icing, as described in this report. Generally, the minimum saturation temperature value used at the plant is 132°F. However, due to variability in conditions that create a saturated environment (i.e., relative humidity) as well as the significant consequences of a wet stack operation at CCS, GRE attempts to apply an operating safety margin above the minimum saturated temperature target at the stack (referred to as dry stack operating temperature) such that the gas temperature at the absorber outlets is sufficiently warm.

of the reheat system is to pull ambient air from within the boiler house building, which contains residual heat from all plant processes. The reheat inlet temperature typically runs a steady state of about 80 degrees Fahrenheit (°F) throughout the year. This reheat air is ducted across the outer surface of the economizer ductwork by new fans. The economizer area increases the reheat air temperature. From the reheat fan discharge, the ductwork then passes between the two precipitators gaining more heat before being routed to the scrubber building. Once in the scrubber building, this reheat air is injected into the flue stream immediately downstream of the absorber outlet. (See Figure 2-4.)

For illustrative purposes, Figure 2-2 provides a basic profile view of the flue gas reheat ductwork and corresponding tie-ins in the boiler house building and the scrubber building.

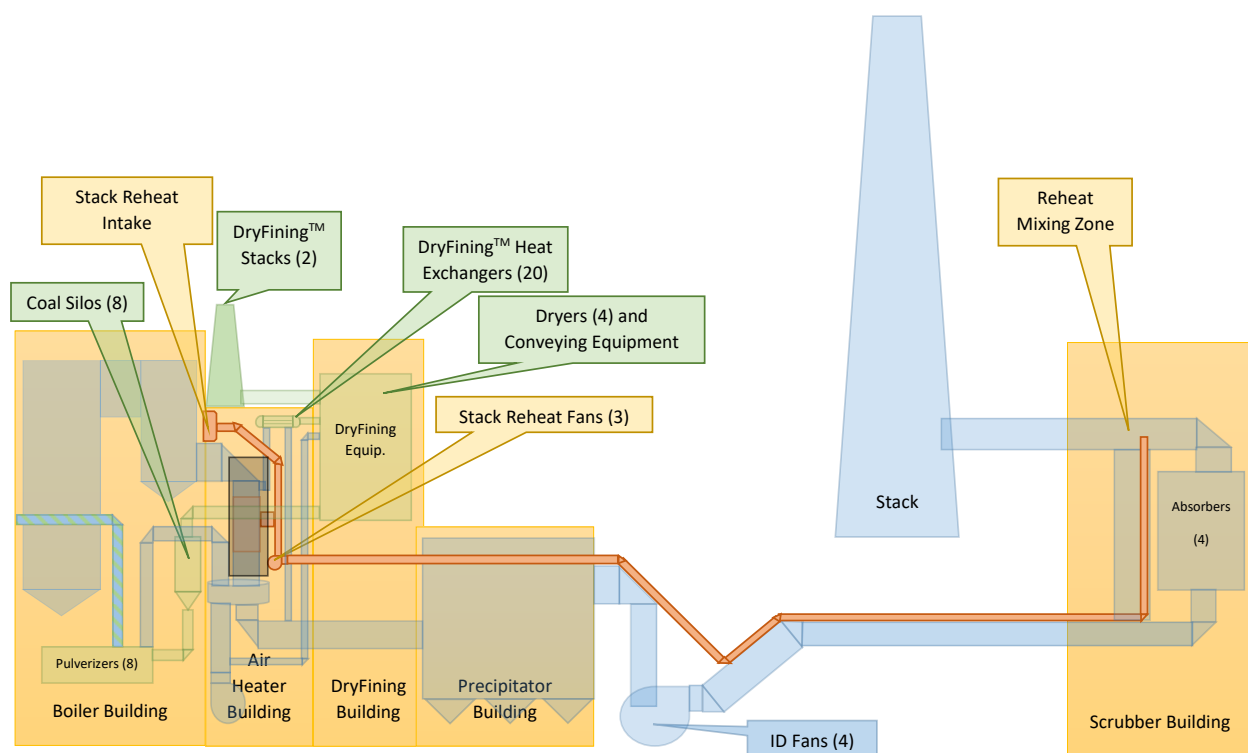

Figure 2-2: Illustration of CCS Flue Gas Reheat System

In 2014, the NDDEQ approved installation of the flue gas reheat systems for Units 1 and 2.¹⁵ In 2017, the flue gas reheat systems began operation. Use of this reheat system in concert with DryFining™ has allowed GRE to maintain compliance with the SO₂ BART limit of 0.15 lb/MMBtu on a 30-day rolling average basis. Figure 2-3 provides an illustration of Unit 1 SO₂ emissions on a lb/MMBtu basis before and

¹⁵ December 1, 2014 letter from Terry O'Clair of the NDDEQ to Deb Nelson of GRE.

after installation of the flue gas reheat design. Unit 2's SO₂ emissions reduction trend is consistent with Unit 1.

Figure 2-3: Unit 1 SO₂ Emissions Reductions After Implementation of the Flue Gas Reheat System

However, upon completion of the flue gas reheat installation, GRE observed that the reheat system did not meet design criteria. Specifically, the reheated air provided only ~200°F to the reheat mixing zone, rather than the 300°F design. This was due to an error in the modeling in which the surface of the economizer duct was assumed to have minimal temperature losses and would remain at approximately 780°F. The actual temperature loss of the economizer ductwork with the reheat system was found to decrease the economizer side walls to roughly 320°F, significantly less than the 780°F design value. The net effect was lower-temperature reheat mixing air. The resulting stack temperature could not be maintained at 10°F to 12°F above saturation temperature¹⁶ at full unit load, which was the minimum

¹⁶ See footnote 15, which describes saturation temperature.

design specification. This target flue gas temperature range is generally referred to herein as dry stack operation.

The installed flue gas reheat system only increases stack temperature by approximately 2°F above the saturation temperature at full load. GRE also observed that the volume of dry reheat mixing air decreases the adiabatic saturation temperature by roughly 3°F, thus resulting in a total reheat system benefit of approximately 5°F above saturation at full load. This is a very narrow margin for dry stack operation given the inherent variability and dynamic nature of functional and meteorological parameters for all operating conditions.

During non-cold weather and at full unit load with all coal dryers in operation, the stack reheat system is capable of maintaining dry stack operation such that the proportion of boiler flue gas to the wet scrubber may be maximized. However, by increasing flue gas volume to the scrubber, less of un-scrubbed hotter gas is bypassed, thus consuming the margin in the system needed to maintain a dry stack. As a result, in the following circumstances, the scrubber bypass may need to be opened to a certain degree to maintain dry stack conditions:

1. At reduced unit load, flue gas temperature cannot be sustained above the saturation point, since the plant is producing less thermal energy for the reheat system. As the available level of heat degrades, the temperature of the reheat air is reduced, increasing the risk that the stack will become wet.
2. During extended cold weather periods, the stack temperature cannot be sustained above the saturation point due to both heat losses throughout the reheat ductwork and denser ambient air to the boilers.¹⁷

For example, during a recent winter test case, GRE staff confirmed that at mid-load (~350 MW) operation, the heat absorbed by the equipment and duct work dissipated, which significantly degraded the effectiveness of the reheat system. Had the test continued for a prolonged period, plant staff anticipated a wet stack condition. The test ended prior to observing a wet stack condition, but this example demonstrates the need to have the scrubber bypass available to increase stack temperature safely above the saturation level.

In these aforementioned circumstances, the scrubber bypass must be opened slightly to allow hotter, drier gases to increase the gas temperature at the absorber outlets to the stack. Figure 2-4 provides a basic cutaway illustration of the interface between the scrubber bypass dampers and flue gas reheat ductwork at the outlet of the four scrubber (absorber) modules.

¹⁷ "Cold" is used to describe weather conditions that create the need for additional reheat, requiring more flue gas to bypass the scrubber to maintain dry stack operation. Cold weather is a function of temperature, wind speed, and other weather factors that cause significant cooling of the power plant equipment and flue gases.

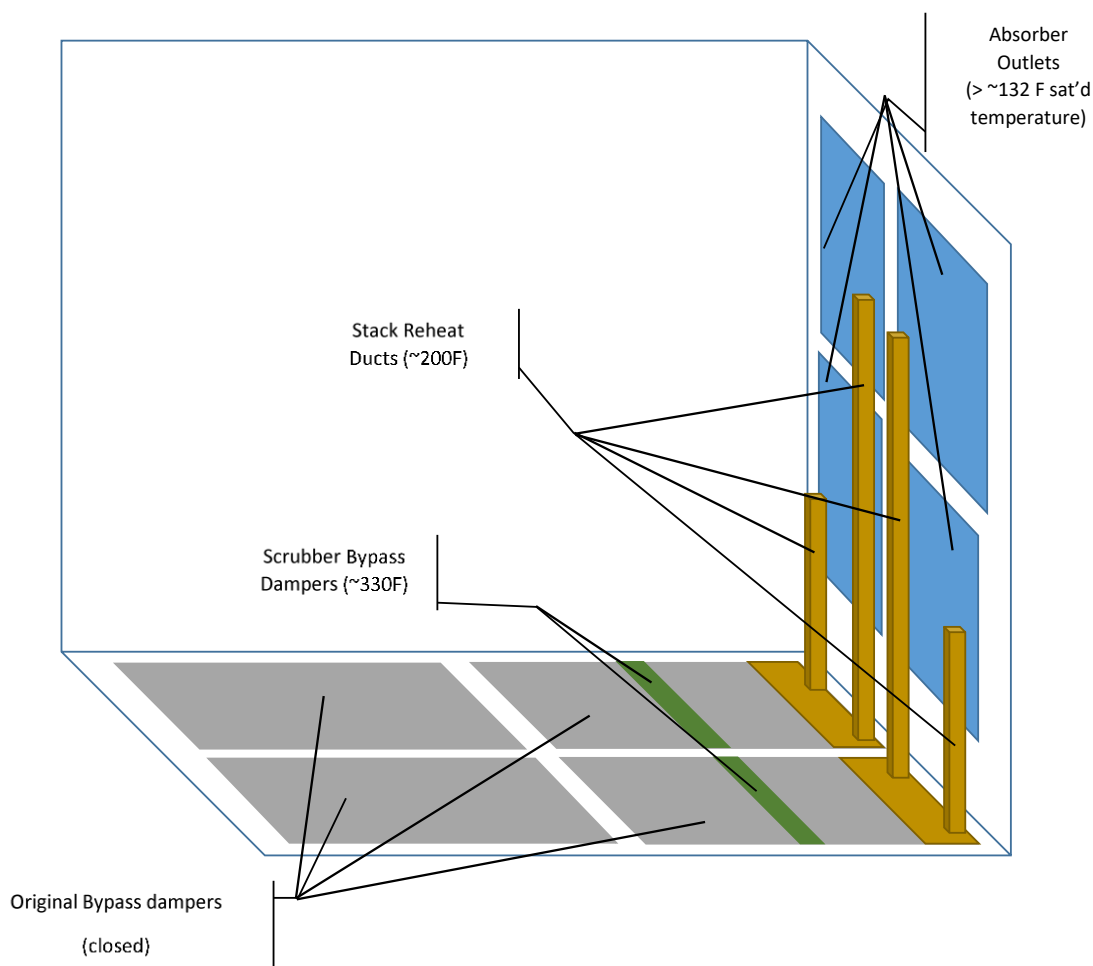

Figure 2-4: Cutaway Illustration of Interface between Scrubber Bypass Dampers and Flue Gas Reheat Ducts at the Absorber Module Outlets

2.4 Recent Reheat Optimization Assessments

Given that the novel flue gas reheat system was commissioned in 2017, GRE has had relatively limited operational experience with it over the full range of operation. Since the commissioning of this system, GRE has conducted two optimization assessments to better understand and identify the limits of its operation, specifically to test the level of SO₂ control performance at high load and non-cold weather conditions and during variable load and colder weather operation. These optimization assessments are detailed in this section as the 2017 and 2019 winter test cases.

2.4.1 2017 Winter Test Case

The 2017 winter test case was performed in February and March 2017 at Unit 2 to better understand the optimal level of SO₂ control performance (i.e., maximum proportion of flue gas routed to the wet

scrubber) below 0.15 lb/MMBtu that could be achieved for short periods and at varying loads and weather conditions.

Throughout the duration of this first test, GRE observed several periods when the stack temperature dropped to lower than the saturation point, indicating high potential for wet stack conditions. Figure 2-5 provides the hourly Unit 2 SO₂ emissions data on a lb/MMBtu basis for the period February 4 through March 8 at Unit 2. The hourly Unit 2 load (MW) during this period is shown on the secondary axis. The green-filled areas demonstrate periods when the stack temperature was less than 130°F. At other times, SO₂ emissions increased for short periods due to low unit load or absorber cleaning.

Figure 2-5: Winter 2017 Test Case Results of Unit 2 SO₂ Emissions v. Load

GRE observed a correlation between low load and decreased stack temperature, unless the scrubber bypass damper is opened to allow hot, unsaturated flue gas to mix with the scrubbed gas. Figure 2-6 compares the Unit 2 load with stack temperature. In every instance that the unit load was reduced by at least half of its maximum capacity, the stack temperature rapidly decreased to levels that approached or reached saturation levels. As in the previous figure, the green shaded areas demarcate generally when the stack temperature was less than 130°F.

Figure 2-6: Winter 2017 Test Case Results of Unit 2 Load v. Stack Temperature

2.4.2 2019 Winter Test Case

GRE conducted a second assessment during winter to both optimize scrubber performance and to gather additional data on flue gas reheat at high unit load averaging 595 MW while maintaining dry stack. Over approximately a four-week period, GRE attempted to operate Unit 2 at an SO₂ emissions performance level of approximately 0.10 lb/MMBtu while monitoring for wet stack conditions and any other operational issues. The test concluded with a unit outage to inspect the physical characteristics of the emissions control system. Figure 2-7 illustrates the daily average SO₂ emissions performance and the corresponding stack temperature measured during the test with certain days shaded for emphasis as follows:

- The days with green-shaded areas indicate that an absorber cleaning event occurred, so one of the four scrubber modules was out of service for a few hours on those days.
- The two days (March 1 and 2) encircled in the blue shaded area demarcate a significant reduction in daily ambient temperature that occurred during the test. The daily average temperature dropped 22°F between February 28 and March 2, with the single-day decline of 17°F (from 9°F

to -8°F) between March 1 and 2 being the most significant single-day ambient temperature decrease.

Figure 2-7: Winter 2019 Test Case Results of Daily Unit 2 SO₂ Emissions v. Stack Temperature

GRE made the following key observations during this second test:

1. The lowest stack temperature recorded of 133.8°F on March 2 corresponded to the most significant day-to-day decline in ambient temperature and one of the lowest daily ambient temperature readings during the test of -9°F. However, ambient temperatures observed during the test did not reach the level of extreme cold that CCS experiences each winter, with the lowest hourly temperature of -15°F occurring on March 3. The lowest recorded stack temperature during the test was within 2°F of what is generally considered the saturation temperature of 132°F and is less than the targeted dry stack operating temperature.
2. Broken and cracked duct stiffeners were observed during the outage. An inspection of the broken stiffeners revealed heavy corrosion. Upon more detailed cleaning and inspection, corrosion was present on all stiffeners with the worst conditions on the downstream airflow side. It is suspected

that moisture collected on the front of the stiffeners was blown to the back where it resided, which may explain more corrosion on the back of the stiffeners. Although this area historically has required some patch repairs, the extent of corrosion and damage was unexpected in this outage. Without a detailed history of inspections and corrosion rates, it is difficult to causally relate the increased scrubbing during the four-week test to the evidence of accelerated damage in this area.

3. The stack drains did not have any liquid and there were no stack opacity spikes. An opacity spike can be an indication of excessive moisture in the stack. However, evidence of moisture was observed on new stack view ports in the mid-level area of the stack. Additionally, the entire breeching area was moist, and two of the four stack drains were plugged with solid material or precipitate, indicating moisture was potentially present.

In summary, Unit 2 SO₂ emissions performance averaged ~0.10 lb/MMBtu (0.104 lb/MMBtu) for this short duration test, understanding that longer term effects are difficult to assess from this test, especially given the unfavorable observations made with respect to the integrity of the equipment internals observed during the outage.

2.4.3 Low Load Reheat Augmentation System

These two optimization assessments in 2017 and 2019 indicate that the emissions control systems are capable of improved SO₂ emissions performance levels for short periods of time, while fully understanding that there are potential long-term operational risks. As a measure to potentially mitigate or better manage the risk of a wet stack, especially at low load conditions, GRE is in the process of installing an emergency heat source, termed Low Load Reheat Augmentation System, that is expected to be ready for use as needed in 2020. The design of this system is to temporarily reroute some air from an existing forced draft fan to the existing reheat system. The additional air flow and thermal energy is intended to maintain a stack temperature safely above the saturation temperature.

The system is designed as a contingency to be used during low load operating conditions and when there is potential for wet stack (i.e., increased opacity levels, measured stack temperature approaching possible saturation conditions, presence of liquid in stack drains) in order to maintain a dry stack operating temperature. Accordingly, use of this system only in these infrequent situations to support an incremental level of additional flue gas to the wet scrubber is expected to not appreciably affect annualized SO₂ emissions on a mass basis.

2.5 Updated Baseline SO₂ Emissions Performance Level

As a result of GRE's test efforts in the last two years to better understand the opportunities and implications of improved SO₂ emissions performance, GRE proposes to adjust its annual SO₂ emissions to be reflective of a performance level less than the current BART limit of 0.15 lb/MMBtu. Specifically, through a permitting action to be completed via the NDDEQ's permit to construct regulatory program at NDAC 33.1-15-14, GRE seeks an annual-average mass emissions limit of 626 lb/hr that is equivalent to

0.104 lb/MMBtu at full load, as described in Section 3.8.¹⁸ This performance level is consistent with operation of multiple emissions control measures, namely the wet scrubber system, DryFining™ technology, and flue gas reheat applications at Units 1 and 2.

This baseline emissions update is in alignment with the 2019 RH SIP Guidance with respect to evaluating a projected scenario for baseline emissions. At page 29 in the section entitled "Baseline control scenario for the analysis," excerpted below, EPA considers the projected 2028 emissions scenario as a "reasonable and convenient choice" for the baseline control scenario:

"Typically, a state will not consider the total air pollution control costs being incurred by a source or the overall visibility conditions that would result after applying a control measure to a source but would rather consider the incremental cost and the change in visibility associated with the measure relative to a baseline control scenario. The projected 2028 (or the current) scenario can be a reasonable and convenient choice for use as the baseline control scenario for measuring the incremental effects of potential reasonable progress control measures on emissions, costs, visibility, and other factors. A state may choose a different emission control scenario as the analytical baseline scenario. Generally, the estimate of a source's 2028 emissions is based at least in part on information on the source's operation and emissions during a representative historical period. However, there may be circumstances under which it is reasonable to project that 2028 operations will differ significantly from historical emissions. Enforceable requirements are one reasonable basis for projecting a change in operating parameters and thus emissions; energy efficiency, renewable energy, or other such programs where there is a documented commitment to participate and a verifiable basis for quantifying any change in future emissions due to operational changes may be another. A state considering using assumptions about future operating parameters that are significantly different than historical operating parameters should consult with its EPA Regional office."

Section 3.8 provides additional detail on the proposed mass emissions rate limit for SO₂ at Units 1 and 2 following the four-factor analysis of additional emissions control measures.

¹⁸ 626 lb/hr = 0.104 lb/MMBtu x 6,015 or 6,022 MMBtu/hr rated capacities for Unit 1 and 2 listed in the Title V operating permit.

3 Sulfur Dioxide (SO₂) Four-Factor Analysis

GRE has completed a four-factor analysis of additional SO₂ emissions control technologies and optimizations at CCS Units 1 and 2 above and beyond those described in Section 2.

Section 3.1 summarizes the four-factor analysis approach with respect to the regional haze program detailed in the 2019 RH SIP Guidance. Sections 3.2 and 3.3 identify and describe various SO₂ control measures. Sections 3.4 through 3.7 evaluate the four statutory factors to CCS Units 1 and 2. Section 3.8 proposes an SO₂ emissions limit and control measures.

3.1 Four-Factor Analysis Approach

Consistent with EPA's guidance and NDDEQ direction, GRE has completed a four-factor analysis as summarized in Sections 3.1.1 to 3.1.5.

3.1.1 Identify all Emission Control Options

Prior to completing a four-factor analysis of each emissions control technology, all commercially available and technically feasible emission control options for CCS Units 1 and 2 must first be identified. Potentially available emission control options include both add-on control equipment and process improvement applications. All control options identified as available and technically feasible are then evaluated against the "four factors."

In order to be considered available and technically feasible, an emissions control must have been previously installed and operated successfully on a similar source under similar physical and operating conditions. Novel controls that have not been demonstrated on full-scale, coal-fired utilities are not considered as part of this analysis. Instead, this evaluation focuses on commercially demonstrated control options.

The control effectiveness of currently available retrofit technologies ranges from 40% to 98+%. For purposes of this analysis, GRE evaluated only those technologies that have the potential to achieve an overall SO₂ reduction greater than the performance of the existing systems, including optimizations.

Sulfur emissions from coal combustion consist primarily of SO₂, with a much lower quantity of SO₃ and gaseous sulfates. These compounds form in the coal as organic and pyritic sulfur. Either form is oxidized during the combustion process. For permitting and design purposes, it is assumed that 100% of the fuel sulfur will convert to SO₂ during the combustion process, and that 1% of the uncontrolled SO₂ will oxidize to SO₃. Theoretically, several techniques can be used to reduce SO₂ emissions from coal combustion sources and they are grouped into pre-combustion controls and post combustion controls, which further subdivide into wet and dry technologies, as summarized in Table 3-1.

Table 3-1: Additional SO₂ Control Measures with Potential Application at CCS Units 1 and 2

Control Technology

An evaluation of additional pre-combustion and post-combustion SO₂ emissions control measures to CCS Units 1 and 2 are described in Sections 3.2 and 3.3, respectively.

3.1.2 Factor #1 – Cost of Compliance

Factor #1 considers and estimates, as needed, the capital and annual operating and maintenance (O&M) costs of the control measure. As directed by the 2019 RH SIP Guidance at page 21, costs of emissions controls follow the accounting principles and generic factors from the EPA Air Pollution Control Cost Manual (EPA Control Cost Manual)¹⁹ unless more refined site-specific estimates are available. Under this step, the annualized cost of installation and operation on a dollars per ton of pollutant removed (\$/ton) of the control measure, referred to as “average cost effectiveness,” is compared to a cost effectiveness threshold that is estimated by the NDDEQ.

Generally, if the average cost effectiveness is greater than the threshold, the cost is considered to not be reasonable, pending an evaluation of other factors. Conversely, if the average cost effectiveness is less than the threshold, then the cost is considered reasonable for purposes of Factor #1, pending an evaluation of whether the absolute cost of control (i.e., costs in absolute dollars, not normalized to \$/ton) is unreasonable. This situation is particularly applicable to a source with existing emissions controls with

¹⁹ US EPA, “EPA Air Pollution Control Cost Manual, Sixth Edition,” January 2002, EPA/452/B-02-001. The EPA has updated certain sections and chapters of the manual since January 2002. These individual sections and chapters may be accessed at <https://www.epa.gov/economic-and-cost-analysis-air-pollution-regulations/cost-reports-and-guidance-air-pollution> as of the date of this report.

an intermediate or high degree of effectiveness, as is the case at CCS Units 1 and 2 due to its existing SO₂ emissions controls.

The cost of an emissions control measure is derived using capital and annual operation and maintenance (O&M) costs. Capital costs generally refer to the money required to design and build the system. This includes direct costs, such as equipment purchases, and installation costs. Indirect costs, such as engineering and construction field expenses and lost revenue due to additional unit downtime in order to install the additional control measure(s), are considered as part of the capital calculation. Annual O&M costs include labor, supplies, utilities, etc., as used to determine the annualized cost in the numerator of the cost effectiveness value. The denominator of the cost effectiveness value (tons of pollutant removed) is derived as the difference in: 1) projected emissions using the current emissions control measures (baseline emissions), as described in Section 2.5, in tons per year (tpy), and 2) expected annual emissions performance through installation of the additional control measure (controlled emissions), also in tpy.

For purposes of calculating cost effectiveness, GRE uses the updated baseline emissions value of 626 lb/hr, as described in Section 2.5, in conjunction with projected utilization (also called annual capacity factor or ACF) of the unit to determine an annual tpy value.²⁰ Over the past 10 years, CCS averages 87% plant utilization, as shown in Table 3-2. GRE considers this value representative of projected operations for purposes of determining annualized emissions. The product of the 626 lb/hr value and 87 percent ACF converted to a tpy basis is 2,385 tpy SO₂ for each unit as the baseline annual emissions rate to be used for purposes of determining annual emissions reductions for a given additional control measure.

²⁰ Annual capacity factor is defined by EPA (40 CFR 60 Subpart Dc) as "... the ratio between the actual heat input to a steam generating unit from an individual fuel or combination of fuels during a period of 12 consecutive calendar months and the potential heat input to the steam generating unit from all fuels had the steam generating unit been operated for 8,760 hours during that 12-month period at the maximum design heat input capacity..." Because the proposed mass SO₂ emissions limit is based on the maximum rated heat input capacity to the boiler, the annual capacity factor is a reasonable representation to determine projected annual heat input duty for purposes of this analysis. Unit outages are considered in the annual capacity factor calculation.

Table 3-2: Annual Average Capacity Factors at CCS Unit 1 and Unit 2

Year	Annual Capacity Factor	
	Unit 1	Unit 2
2009	94.2%	92.7%
2010	93.8%	79.6%
2011	81.6%	89.0%
2012	92.4%	90.9%
2013	92.4%	83.3%
2014	87.8%	88.2%
2015	89.3%	87.3%
2016	86.3%	72.9%
2017	70.8%	85.0%
2018	91.6%	90.5%
10 yr Average	88%	86%
Plant Average	87%	

The calculated cost effectiveness value for each control measure is compared to a cost effectiveness threshold established by the NDDEQ. The NDDEQ's original BART cost thresholds were based on the "high cost" value of \$3,000 per ton listed in the June 1999 WRAP Annex to Grand Canyon Visibility Transport Commission (GCVTC) Report.²¹ This 1999 value is scaled to today's dollars using the Chemical Engineering Plant Cost Index (CEPCI).²² The CEPCI is an industrial plant index that is considered more representative for purposes of this analysis than general cost indices such as the Consumer Price Index (CPI). The average cost effectiveness threshold in current dollars is calculated to be \$4,630 per ton.²³

²¹ Cited by EPA in the "Regional Haze Regulations and Guidelines for Best Available Retrofit Technology (BART) Determinations" proposed rule; 69 FR 25198; May 5, 2004.

²² More information on CEPCI may be found at this link: <https://www.chemengonline.com/pci-home>. The CEPCI is accessible by subscription through "Chemical Engineering" magazine. The CEPCI scaling factors for this analysis compare 1999 values to December 2018 values.

²³ The NDDEQ also calculated an incremental cost effectiveness (cost effectiveness between two control measures) threshold in addition to the average cost effectiveness threshold for the BART evaluations. Pursuant to a June 1, 2018 teleconference between GRE and NDDEQ staff, the NDDEQ stated that the average cost effectiveness and absolute costs of an additional control measure will be considered, but incremental cost effectiveness will not be evaluated for purposes of the screening level analysis.

3.1.3 Factor #2 – Time Necessary for Compliance

Factor #2 is considered by NDDEQ in setting reasonable deadlines for the selected control. This includes the planning, installation and commissioning of the selected control.

For purposes of this analysis and if a given SO₂ control measure requires a unit outage as part of its installation, GRE considers the forecasted outage schedule for Units 1 and 2 in conjunction with the expected timeframe for engineering and equipment procurement following NDDEQ and EPA approval of the given control measure.

3.1.4 Factor #3 – Energy and Non-air Environmental Impacts:

Factor #3 involves consideration of the energy and non-air environmental impacts of each control measure. Non-air quality impacts may include solid or hazardous waste generation, wastewater discharges from a control device, increased water consumption, and land use. The environmental impact analysis is conducted based on consideration of site-specific circumstances.

The energy impact analysis considers whether use of an emissions control technology results in any significant or unusual energy penalties or benefits. Energy use may be evaluated on an energy used per unit of production basis, energy used per ton of pollutant controlled, or total annual energy use.

3.1.5 Factor #4 – Remaining Useful Life of the Source

Factor #4 is the remaining useful life of the source, which is the difference between the date that additional emissions controls will be put in place and the date that the facility permanently ceases operation. Generally, the remaining useful life of the source is assumed to be longer than the useful life of the emissions control measure unless there is an enforceable cease-operation requirement. In the presence of an enforceable end date, the cost calculation can use a shorter period to amortize the capital cost.

For the purpose of this evaluation, the remaining useful life of both Unit 1 and Unit 2 is assumed to be longer than the useful life of the additional emission controls measures. Therefore, the expected useful life of the control measure is used to calculate the emissions reductions, amortized costs, and the resulting cost per ton (\$/ton).

3.2 Identification of Pre-Combustion Controls

As introduced in Section 2.1, GRE developed and commercialized a novel multipollutant control technology, described as DryFining™. At issue is the question of whether there is any opportunity to further optimize this pre-combustion technology. In theory, either more high-density segregation could be achieved to remove pyritic sulfur, or more moisture could be removed in order to increase the proportion of flue gas that may be routed to the wet scrubber instead of the scrubber bypass.

For purposes of SO₂ emissions control, DryFining™ is a two-stage process, beginning with an air jig that separates higher density coal, containing some pyritic sulfur, before routing the coal to the next stage.

GRE's plant engineering staff have reviewed alternative techniques for improving pyritic segregation but have not found anything to impact SO₂ at the stack.

With respect to stage 2 after the air jig, the coal is moved through fluid bed dryers using plant waste heat to reduce its moisture content. This dried coal provides many benefits, including that it improves plant heat rate, which reduces plant energy use and, with respect to SO₂, reduces flue gas volume thus allowing more of the flue gas to be scrubbed.

There is a limit to the effectiveness of the coal drying stage without causing negative environmental consequences.²⁴ Each CCS unit was designed with four dryers, so eight total dryers are installed. The plant can produce enough dried coal to operate at full load with seven dryers in service. Therefore, one dryer can be out of service for maintenance while still maintaining emission rates. In theory, this extra dryer could be used to process (i.e., dry) coal to a lower moisture content; however, in practice, this would be environmentally detrimental.

When the dryers are operating properly, the plant can decrease coal moisture by 10% to 12%. As removal approaches 12%, the plant begins to experience significant operational issues such as auto-ignition of coal in bunkers in addition to difficulties maintaining steam temperature. Specifically, DryFining™ increases the heat content of coal from ~6,300 to ~6,700 Btu/lb. When the coal reaches very high Btu values for the design of Units 1 and 2, the fireball becomes too hot at a lower location in the boiler. The water walls absorb most of the heat and it thus does not reach the upper area of the boiler necessary to maintain steam temperature. To combat this, the burner tilts are changed to raise the fireball higher to get better heat transfer in the upper part of the boiler and to maintain steam temperature to the turbine. Changing the burner tilts in this way will, in and of itself, negatively impact NO_x emissions performance.

In summary, after almost a decade of operating DryFining™ technology at Units 1 and 2, GRE has fully optimized its ability to reduce SO₂ as a pre-combustion control measure.

3.3 Identification of Post-Combustion Controls

The flue gas desulfurization (FGD) systems commonly used to control SO₂ emissions can be classified as either dry or wet systems. As implied by the name, dry scrubbers require less water than wet systems but also require higher temperatures to ensure that all moisture has been evaporated before leaving the scrubber. Wet systems are generally capable of achieving higher removal efficiencies than dry systems because it is easier to mix a gas with a liquid than a solid.

FGD systems require the use of an alkali powder or slurry. Lime (or limestone) is the most widely used compound for acid gas absorption. Wet FGD systems may discard all the waste by-product streams or

²⁴ DryFining™ is a multipollutant technology that, in part, reduces mercury, SO₂ and NO_x emissions. While this evaluation is focused on SO₂, drier coal beyond that currently targeted will negatively impact NO_x emissions.

regenerate and reuse them. Wet systems generally require more extensive networks of pumps and piping than dry systems to recirculate, collect and treat the scrubbing liquid.

There are three main FGD systems including wet scrubbing, spray dryer absorption, and dry sorbent injection. CCS Units 1 and 2 currently operate with a wet scrubber.

3.3.1 Dry Sorbent Injection

Dry sorbent injection involves the injection of a lime, limestone or even sodium powder into the exhaust gas stream. The flue gas is then routed through a baghouse or electrostatic precipitators to remove the sorbent and entrained SO₂. The process was developed as a lower cost FGD option because the mixing occurs directly in the exhaust gas stream instead of in a separate tower. Depending on the residence time and gas stream temperature, sorbent injection control efficiency is typically between 50% and 70%. While dry sorbent injection is a technically feasible retrofit option, given that the maximum expected removal efficiency of this technology is approximately 70%, it will not provide improvement over CCS's existing SO₂ emissions control system and is therefore not evaluated further for this analysis.

3.3.2 Spray Dry Absorption

Spray dry absorption is a dry scrubbing system that sprays a fine mist of lime slurry into an absorption tower where the SO₂ is absorbed by the droplets. The absorption of the SO₂ leads to the formation of calcium sulfite (CaSO₃•2H₂O) and calcium sulfate (CaSO₄) within the droplets as illustrated by equations 1 and 2 below.

The liquid-to-gas ratio is such that the heat from the exhaust gas causes the water to evaporate before the droplets reach the bottom of the tower. This leads to the formation of a dry powder that is collected with a fabric filter. Spray dryer absorption control efficiency is typically in the 70% to 90% range. A spray dry scrubber is a technically feasible control option, but it will not provide improvement over the existing removal efficiency and is therefore not evaluated further as part of this analysis.

3.3.3 Wet Lime/Limestone Scrubbing

Wet lime/limestone scrubbing involves scrubbing the exhaust gas stream with a slurry comprised of lime (CaO) or limestone (CaCO₃) in suspension. The process takes place in a wet scrubbing tower located downstream of a particulate matter control device. Similar to the chemistry illustrated above for spray dry absorption, the SO₂ in the flue gas reacts with the lime or limestone slurry to form calcium sulfite (CaSO₃•2H₂O) and calcium sulfate (CaSO₄).

There are two basic types of wet scrubber technologies: natural oxidation and forced oxidation. For new installations, forced oxidized scrubbers are capable of achieving 98+% control. Both Coal Creek units have

natural oxidation scrubbers. GRE estimates that the existing wet scrubbers control SO₂ to approximately 94% to 95%, based on the proposed permitted mass emissions limit that is calculated from a 0.104 lb SO₂/MMBtu performance level as well as some bypass leakage as provided in the analysis from a third-party engineering firm.^{25,26} Theoretically, with a completely closed and sealed flue gas system and a new “wet” stack, the existing scrubber performance would improve only to approximately 96%. This estimate is specific to the scrubber/absorber proper and does not include upstream SO₂ emissions control that results from DryFining™ air jig operations.

As described in GRE’s CCS BART report,²⁷ several wet scrubber modifications were assessed. These included the addition of a fifth scrubber module and expansion of the existing absorber towers to scrub all the flue gas. With the implementation of DryFining™, the flue gas volume was reduced such that the existing scrubber modules could handle 100% of the flue gas, notwithstanding that the current stacks are designed as dry stacks, as detailed in Sections 2.2 through 2.4. Therefore, the fifth absorber module and/or expanded absorber towers are no longer needed. Further, conducting a four-factor evaluation to replace the existing wet scrubber system with a new design for a possible incremental level of improved SO₂ performance (and which would also require one of the two projects described in Section 3.3.4) will inherently result in unreasonable costs on absolute cost and average cost effectiveness bases.

3.3.4 Increase Amount of Flue Gas to Existing Wet Scrubbers

As a potential method to reduce SO₂, a greater proportion of the unit’s flue gas could be routed to the existing wet scrubbers if additional control measures are taken. As detailed in Sections 2.2 through 2.4, a relatively minor bypass is currently needed in limited situations to maintain dry stack conditions. If new wet stacks are installed or if a natural gas-fired reheat system is implemented, as considered in Sections 3.3.4.1 and 3.3.4.2, then theoretically there would no longer be a need to bypass the scrubbers. In this scenario, some un-scrubbed flue gas would still leak through the scrubber bypass dampers, which are not designed to be completely sealed and are estimated to add approximately 0.007 lb SO₂/MMBtu to the total SO₂ emissions rate.

In total, based on testing with scrubber bypass closed and accounting for future variability in operations, GRE estimates that the annual emissions from either technology will improve SO₂ performance to a level of 0.08 lb/MMBtu, representing an approximately 20% improvement from the proposed permit level that

²⁵ The SO₂ emissions rate is not directly measured in the flue gas to the wet scrubbers. Because DryFining™ serves as a pre-combustion SO₂ control and due to the minor proportion of flue gas that is required to bypass the scrubber to maintain a dry stack, it is incorrect to conclude that the difference in SO₂ at the stack versus the sulfur in the incoming coal is solely a function of wet scrubber performance.

²⁶ URS Corporation, “GRE Coal Creek Units 1 & 2 Review of Options to Reduce SO₂ Emissions,” October 26, 2004. This slide deck was included in the December 2007 GRE CCS BART Report.

²⁷ GRE, “Coal Creek Station Units 1 and 2 Best Available Retrofit Technology Analysis,” revised December 12, 2007.

is based on 0.10 lb/MMBtu. The resulting average annual expected emissions reduction for each unit is 550 tpy, calculated as the difference in the baseline emissions of 2,385 tpy calculated in Section 3.1.2 and the controlled emissions rate of 1,835 tpy, calculated as the product of 6,019 MMBtu/hr (average of the two rated heat input capacities for Units 1 and 2), 0.080 lb SO₂/MMBtu performance, and 87% ACF.

3.3.4.1 Replace Current Stack with Wet Stack

As detailed in Section 2.2, Coal Creek has a unique emission control configuration, coupling a wet scrubber with a dry stack and novel flue gas reheat system. It is not possible to convert the existing stack to a wet stack design. Instead, a new wet stack would need be installed and the current stack would be abandoned for each unit.

A screening-level four-factor analysis is provided for the project to replace the Unit 1 and 2 stacks in their entirety with wet stacks. For this evaluation, Hamon Custodis, Inc. (Custodis) was engaged to provide a budgetary quote for a new wet stack, excluding foundation and tie-ins. Custodis provided an initial high-level concept to effectively replace the two existing stacks with a “rough budget price.”²⁸ GRE has added to this price a high-level and conservatively low set of cost estimates to convert the Custodis cost to an appropriate diameter and to include foundations, duct work, and continuous emissions monitoring systems (CEMS).

3.3.4.2 Natural Gas Reheat System

As detailed in Section 2.3, the novel flue gas reheat system is capable of maintaining a dry stack under most, but not all, operational situations, while maximizing the proportion of flue gas to the wet scrubber. During low load and cold weather operation, the existing reheat system does not provide enough thermal energy to reheat the stack gas to a dry state. There is no significant additional heat in the buildings or equipment that can be scavenged to be used for the current flue gas reheat system; therefore, GRE has considered the additional control measure of a natural gas-fired reheat system. A screening-level four-factor analysis is provided for the project to replace the existing flue gas reheat system with a natural gas-fired reheat system.

In order to maintain dry stack operation, GRE estimates approximately 31.5 MMBtu/hr of additional heat would be required. For reference, the existing reheat system adds approximately 11 MMBtu/hr, which would be abandoned at an estimated \$12 million/unit loss. Therefore, the new natural gas reheat system is sized at 31.5 MMBtu/hr per unit. The most logical location for a natural gas fired duct burner is adjacent to the current reheat mixing zone. See Figure 2-2 and Figure 2-4 for illustrations of the current flue gas reheat system.

²⁸ April 5, 2019 email from David Durham of Custodis to Loren Loritz of GRE.

Two companies were engaged to provide estimates to support this evaluation. Given that Coal Creek does not currently have a gas supply, WBI Energy (WBI) provided a cost estimate for a new gas line with firm (non-interruptible) gas supply up to Coal Creek's fence line.²⁹ The cost for installation of the natural gas pipeline is split between Unit 1 and Unit 2, because the same pipeline could be used for both sources. GRE plant staff estimated a connecting gas line from the WBI fence line point to the duct burner locations. Barr Engineering (Barr) was engaged to provide an estimate for the natural gas-fired duct burner system. Its high-level (Class 5) estimate of the system was provided with additional consideration for site-specific installation factors.³⁰

3.4 Factor 1 Evaluation – Costs of Compliance

GRE has completed a high-level screening-level cost estimate for the replacement wet stack and natural gas-fired reheat system projects. The capital cost estimates are considered by GRE's plant engineering staff, based on their considerable experience with projects at CCS and their informal conversations with other companies that have completed similar types of projects at power plants, to be conservatively low. A more detailed cost estimate is likely to increase the costs for installing and implementing either of the projects. Importantly, this initial set of cost estimates does not include additional outage time that will very likely be necessary, especially for the replacement wet stack. Cost summary spreadsheets for these two are provided in Appendix A.

The cost effectiveness analysis compares the annualized cost of the technology per ton of pollutant removed and is evaluated on dollar per ton basis using the annual cost (annualized capital cost plus annual operating costs) divided by the annual emissions reduction (tons) achieved by the control device. For purposes of this screening evaluation, a 20-year life (before new and extensive capital is needed to maintain and repair the equipment) at 5.25% interest is assumed in annualizing capital costs.

The resulting cost effectiveness calculations are summarized in Table 3-3.

²⁹ March 20, 2019 email from David Dahms of WBI to Richard Garman of GRE.

³⁰ March 21, 2019 email from Joel Trinkle of Barr to several staff at GRE, forwarding a March 20, 2019 email quote prepared by William Mullinix of Barr.

Table 3-3: SO₂ Control Cost Summary, per Unit Basis

Additional Emissions Control Measure	Installed Capital Cost (\$)	Annualized Capital Cost (\$/yr)	Annual Operating Costs (\$/yr)	Total Annualized Costs (\$/yr)	Annual Emissions Reduction (tpy)	Pollution Control Cost Effectiveness (\$/ton)
New Wet Stack	\$38.8 million	\$3.2 million	\$0.8 million	\$4.0 million	550	7,200
Natural Gas Reheat System	\$14.5 million	\$1.2 million	\$2.2 million	\$3.4 million	550	6,200

The cost effectiveness values of both projects are substantially greater than the cost effectiveness threshold of \$4,630 derived in Section 3.1.2. Therefore, the costs for either retrofit option to replace the current stack with a wet stack or to implement a natural gas-fired reheat system are not reasonable.

Sections 3.5 through 3.7 provide a screening-level summary of the remaining three factors evaluated for the replacement wet stack and natural gas-fired reheat system, understanding that these projects represent substantial capital investments that are not justified on a cost per ton or absolute cost basis.

3.5 Factor 2 Evaluation – Time Necessary for Compliance

Factor #2 estimates the amount of time needed for full implementation of different control measures, which in this case is the replacement wet stack or the natural gas-fired reheat system. Typically, time for compliance includes the time needed to develop and approve the new emissions limit into the state implementation plan (SIP) by state and federal action, then to implement the project necessary to meet the SIP limit via installation and tie-in of equipment for the emissions control measure.

Either projects would require significant resources and time of at least two to three years to engineer, permit, and install the equipment, whether it be a 675-foot-high, 30-foot-inner-diameter chimney or a 10-mile-long, 6-inch-diameter natural gas pipeline with an integrated duct burner system. Subsequently, the new stacks would need to be tied-in to the existing scrubber building, which will likely require several additional days beyond the standard extended outage duration of approximately seven weeks. Similarly, the duct burner systems would need to be tied-in during a subsequent outage after the equipment is built before it can begin operation.

Assuming that a SIP is approved in 2022, then the next set of extended outages for the two units are scheduled to occur in 2025 and 2026 for potentially installing the required technology.

3.6 Factor 3 Evaluation – Energy and Non-Air Quality Environmental Impacts

The energy and non-air environmental impacts associated with implementation of the two technologies are summarized herein.

For the replacement wet stack, the current stacks would be abandoned, resulting in demolition and disposal of a significant amount of materials with associated use of demolition equipment and portable engines to accommodate these activities. Additionally, it is not clear where the new stacks would be located because the property surrounding this area is already being used. Significant planning and logistical issues will need to be addressed in order to locate and tie in these stacks.

The natural gas-fired reheat system creates additional non-SO₂ pollutant emissions associated with combustion of natural gas onsite. Based on an estimated range of emission factors (0.1 to 0.2 lb/MMBtu) and assuming year-round operation of the burner, potential NO_x emissions from each unit range from between 14 and 27 tpy. Combustion emissions from the duct burners will require a permit to construct from NDDEQ.

3.7 Factor 4 Evaluation – Remaining Useful Life

Because CCS will operate for the foreseeable future, a 20-year life is used for each control measure, as described in Section 3.4, to calculate emission reductions, amortized costs and cost effectiveness on a dollar per ton basis.

3.8 Proposed SO₂ Controls and Emissions Rates

This analysis does not support the installation of additional SO₂ control technologies at CCS Unit 1 or Unit 2 beyond those described in Section 2. The two identified control strategies of a replacement wet stack or a natural gas-fired reheat system are not cost effective and have significant implementation concerns.

In consultation with NDDEQ, GRE proposes a federally enforceable SO₂ emissions rate limit of 626 lb/hr as an annualized average (365-boiler-operating-day rolling average) limit for each unit, with plant averaging between the two units.³¹ GRE proposes to implement operational practices consistent with those summarized in Section 2.5 in order to comply with the proposed SO₂ emissions rate limit, effective upon approval of a federally enforceable permit to construct issued by NDDEQ. This new performance level

³¹ 626 lb/hr = 0.104 lb/MMBtu x 6,015 or 6,022 MMBtu/hr rated capacities for Unit 1 and 2 listed in the Title V operating permit.

further reduces annual SO₂ emissions at each unit by an estimated 1,050 tpy in comparison to the BART limit.³²

In the 2019 RH SIP Guidance (p. 44), there is the section entitled "Averaging period and units," which prescribes the options for the form of a limit being taken pursuant to this regional haze implementation period. EPA states that the "... Regional Haze Rule also allows SIPs to contain limits on mass emissions during a particular time period (e.g., a cap on 30-operating day mass emissions)." The proposed SO₂ limit is on a mass rate basis instead of a lb/MMBtu basis for the following reasons:

1. It is consistent with a mass emissions rate used in the dispersion modeling analysis to determine the visibility benefits at Class I areas due to application of control measures.
2. It is consistent with a mass emissions rate needed for control cost evaluation purposes, such as when considering other emissions control options and improvements with respect to conducting a regional haze four-factor analysis.
3. As described above, low load conditions may cause higher lb/MMBtu levels due to the lack of available heat to maintain the stack temperature safely above saturation. The lb/hr emission rate is inclusive of these higher lb/MMBtu levels during low load operation.
4. The proposed 626 lb/hr SO₂ limit on a 365-day rolling average in the permit to construct shall be inclusive of all expected operations throughout the year, including low load, planned startups and shutdowns, and maintenance activities such as routine absorber cleanings. An annual average limit that is inclusive of startups and shutdowns aligns EPA's current startup, shutdown, and malfunction (SSM) state implementation plan (SIP) policy.³³

For purposes of clarifying compliance demonstration with this limit, GRE uses the same framework as in 40 CFR 60 Subpart Da for which Units 1 and 2 are already subject. The definition of "boiler operating day" in Subpart Da for a newer boiler is a "24-hour period between 12 midnight and the following midnight during which any fuel is combusted at any time in the steam generating unit." Compliance with the proposed SO₂ limit will be demonstrated using the existing continuous emissions monitoring system (CEMS) by averaging all hourly SO₂ emissions data over each 365-boiler-operating-day rolling average with the first compliance date occurring after 365 boiler operating days of the limit becoming effective when the permit to construct is issued.

³² Comparing the two SO₂ performance levels and applying the 87% annual capacity factor equals an emissions reduction of 1,054 tpy at each unit. $(0.15 \text{ lb/MMBtu BART limit} - 0.104 \text{ lb/MMBtu expected level}) \times (6,015 \text{ or } 6,022 \text{ MMBtu/hr rated capacities for Unit 1 and Unit 2}) \times (87\% \text{ annual capacity factor})$, converted to tpy basis.

³³ EPA's current SSM policy for SIPs is found at 80 FR 33840, June 12, 2015, "State Implementation Plans: Response to Petition for Rulemaking; Restatement and Update of EPA's SSM Policy Applicable to SIPs; Findings of Substantial Inadequacy; and SIP Calls To Amend Provisions Applying to Excess Emissions During Periods of Startup, Shutdown and Malfunction," Final Rule.

Subject: RH2 4 Factor Letter - GRE CCS

Mary Jo,

Based on the tentatively established timeline for Great River Energy's Regional Haze Round 1 report submittal (March 2019), the Department would like GRE to focus their efforts on completing the updated BART analysis associated with Round 1.

This means GRE may delay efforts to complete the analysis required by the May 2, 2018 Regional Haze Second Planning Period letter (due 1/31/19) until further notified by the Department.

Should you have any questions, please let me know. Thanks.

Major power supply changes to reduce costs to member-owner cooperatives (<https://greatriverenergy.com/major-power-supply-changes-to-reduce-costs-to-member-owner-cooperatives/>)

May 7, 2020

Great River Energy plans to replace coal with low cost renewables and market energy purchases

Great River Energy announced plans today to transform its portfolio of power supply resources in the coming years, significantly reducing member-owner wholesale power costs. The electric cooperative plans to phase out remaining coal resources, add significant renewable energy and explore critical grid-scale battery technology.

Great River Energy plans to take the following actions:

**Keeping power reliable
and affordable**

**Continuing to reduce
carbon dioxide emissions**

**Adding cleaner
electricity sources**

- Retire the 1,151-megawatt (MW) Coal Creek Station in the second half of 2022
- Add 1,100 MW of wind energy purchases by the end of 2023
- Modify the 99-MW, coal and natural gas-based Spiritwood Station power plant to be fueled by natural gas
- Install a 1-MW, long-duration battery demonstration system
- Support the repowering of the Blue Flint biorefinery with natural gas

"We are building a power supply portfolio that will serve our member-owner cooperatives for decades," Great River Energy President and Chief Executive Officer David Saggau said. "We are taking advantage of cost-competitive renewables and reliable access to market energy while fostering innovation as the technology of our industry evolves."

Today's announcement follows several changes Great River Energy has made in recent years to seek economic efficiencies in its power supply portfolio. Past analysis has led to decisions to exit a contract for half the output of a Wisconsin coal plant in 2015, retire the coal-based Stanton Station power plant in 2017, close the waste-to-energy Elk River Resource Recovery Project in 2019 and purchase the output of several wind energy projects.

The portfolio changes announced today will significantly reduce Great River Energy's member-owner power supply costs. In addition, the cooperative's power supply resources will be more than 95% carbon dioxide-free, virtually eliminating carbon risk.

"Our power supply plans deliver on our member-owners' three highest priorities: affordability, reliability and environmental stewardship," Saggau said. "Electric cooperatives have a bright future in Minnesota."

Great River Energy plans to purchase more than 1,100 MW from new wind energy projects. This amounts to a more than \$1.2 billion investment in the Midwest's abundant clean energy resources. Great River Energy's renewable capacity is projected to grow from approximately 660 MW in 2020 to more than 1,760 MW by the end of 2023. The Great River Energy board of directors today approved 600 MW of wind energy projects, most of which will be located in Minnesota.

Great River Energy plans to add energy and capacity as needed through upgrades at its fleet of modern, natural gas peaking plants and purchases from the MISO energy market.

Coal Creek Station has been a critical part of Great River Energy's power supply portfolio for decades, but it has lost value compared to other alternatives in recent years. Great River Energy plans to shut down both units of Coal Creek Station during the second half of 2022, although the cooperative is willing to consider opportunities to sell the plant. Coal Creek Station began operations in 1979 in Underwood, North Dakota, and employs 260 people.

"Like all of Great River Energy's decisions, these changes are made in the best interests of our member-owner cooperatives," Saggau said. "Coal Creek Station is operated efficiently, safely and with pride by a dedicated and talented staff. We will make every effort to minimize impacts on our employees and the communities through this transition."

To assist local communities during the upcoming transition, Great River Energy plans to make voluntary annual payments of the local government share of the plant's taxes for five years after the plant's closure.

Great River Energy plans to negotiate an agreement to terminate its steam and water supply contract with Blue Flint, an ethanol biorefinery fueled by process steam from Coal Creek Station. Blue Flint's owner, Midwest AgEnergy, is considering using the contract termination payment from Great River Energy to

reinvest in an economical alternate source for its process heat, thereby benefitting area farmers by continuing to support the local market for corn.

Located near Jamestown, North Dakota, Spiritwood Station is a combined heat and power plant fueled by a combination of DryFine™ lignite coal and natural gas. Great River Energy plans to modify the plant to be fueled with natural gas. The plant generates electricity for the regional electric grid and supplies steam to a nearby ethanol biorefinery.

Great River Energy is working with Form Energy, a battery storage technology developer based in Somerville, Massachusetts, on a first-of-its-kind demonstration of Form's unique long-duration storage technology. The battery project will be a 1-MW, grid-connected storage system capable of delivering its rated power continuously for 150 hours, far longer than the four-hour usage period common among lithium ion batteries. Long-duration storage will help maintain grid reliability in the future during extreme conditions, such as a heat wave or polar vortex. The battery system will be located in Cambridge, Minnesota, and completed in late 2023.

The projects announced today will create hundreds of high-quality construction jobs. "We look forward to partnering with local labor and industry on our projects," Saggau said.

Grand Forks, ND 58203

Re: Regional Haze
Second Planning Period

Dear Mr. Bleth:

The Department of Health (Department) has begun work on the second planning period (Round 2) State Implementation Plan (SIP) for regional haze. In Round 1 of the regional planning process, the emphasis was on Best Available Retrofit Technology (BART) and making reasonable progress towards the national visibility goal. In Round 2, there are no BART requirements; therefore, we will focus on making reasonable progress. The reasonable progress analysis will be made using the four factors in Section 169A(g)(1) of the Clean Air Act:

The four factors are:

1. The cost of compliance
2. The time necessary to achieve compliance
3. The energy and non-air quality environmental impact of compliance; and
4. The remaining useful life of any existing source subject to such requirements

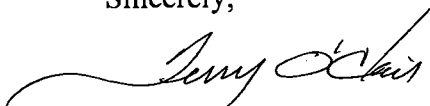

Guidance provided by the U.S. Environmental Protection Agency (Draft Guidance on Progress Tracking Metrics, Long Term Strategies, Reasonable Progress Goals and Other Requirements for Regional Haze State Implementation Plans for the Second Implementation Period at https://www.epa.gov/sites/production/files/2016-07/documents/draft_regional_haze_guidance_july_2016.pdf) indicates the Department must address 80% of the visibility impairment caused by in-state sources. Data from the IMPROVE monitoring sites at Theodore Roosevelt National Park (TRNP) and Lostwood Wilderness Area (LWA) indicate that sulfates and nitrates continue to be the largest contributors to visibility impairment in these areas. The primary precursors of sulfates and nitrates are emissions of sulfur dioxide (SO₂) and nitrogen oxides (NO_x).

Coal-fired electrical generating units have been identified as one of the largest source of sulfur dioxide and nitrogen oxides in North Dakota. Therefore, the Department requests that you prepare a "four factors" analysis for your coal-fired electrical generating units. The analysis should be prepared using the draft EPA guidance noted above. The Department will identify other sources in North Dakota that will be required to submit a four factors analysis.

The Department will be working with the Western Regional Air Partnership (WRAP) to prepare the Round 2 SIP. WRAP will be conducting air quality modeling of regional emissions reductions in early 2019. The Department asks that your "four factors" analysis be submitted by January 31, 2019.

If you have any questions, please contact David Stroh of my staff at (701)328-5188.

Sincerely,

Terry L. O'Clair

RE: Milton R. Young Station Regional Haze Control Study
Second Planning Period

Dear Mr. O'Clair:

As requested in your May 2, 2018 correspondence, I am enclosing three copies of the Regional Haze Control Study (Four Factor Analysis) for Unit 1 and Unit 2 at the Milton R. Young Station.

If you have any questions regarding this study, please contact me at 701-794-8711.

Sincerely,

MINNKOTA POWER COOPERATIVE, INC.

Craig J. Bleth
Senior Manager of Power Production

EXECUTIVE SUMMARY

This report presents the Regional Haze Control Technology (RHCT) analysis for nitrogen oxides (NO_x), and sulfur dioxide (SO₂) for Minnkota Power Cooperative, Inc.'s (Minnkota's) Unit 1 and Square Butte Electric Cooperative's (Square Butte's) Unit 2 at the Milton R. Young Station (MRYS) located near Center, North Dakota. On July 6, 2005, the United States Environmental Protection Agency (U.S. EPA or EPA) finalized the Regional Haze Regulations (RHR) and Guidelines for BART Determinations. In July of 2016, the EPA issued draft guidance for the second implementation period of the regional haze regulations. The guidance document requires a "four factor analysis" to be conducted for sources that have the potential to impair visibility in Class 1 areas. The four statutory factors are:

- The cost of compliance
- The time necessary for compliance
- The energy and non-air quality environmental impacts of compliance, and
- The remaining useful life of the source

This report presents the required "four factor analysis" for MRYS. Note that for MRYS, Minnkota has determined that the "remaining useful life of the source" is not a relevant factor in the analysis. The term "RHCT analysis" is used throughout this report to refer to the analysis that has been conducted in compliance with the requirements of EPA's July 2016 draft guidance.

The guidance document, in general, indicates that the goal of the second implementation period is to look at all sources for incremental visibility improvement including all sources that were previously determined to be Best Available Retrofit Technologies (BART) eligible. Milton R. Young Station Unit 1 and Unit 2 were previously determined to be BART-eligible by the North Dakota Department of Health (NDDH). This evaluation is intended to inform NDDH of the future potential to reduce emissions at Milton R. Young Station and the cost associated with these reductions. This evaluation is based on a top down evaluation of control technologies and will provide NDDH an emission rate for visibility impairment modeling.

There are five predefined steps for conducting a RHCT analysis. Steps 1 through 3 include identifying control technologies, evaluating feasibility, and ranking feasible options by control effectiveness. Step 4 involves a technical evaluation of various impacts related to each feasible control technology. The evaluation reviews include economics, energy, and non-air environmental impacts. This evaluation addresses these first four steps, resulting in an emission rate for the Step 5 Class 1 area visibility impairment impact analysis.

Unlike the previous BART analysis, this analysis reviews technologies on a 'Top Down' basis. The best (lowest emitting) feasible technology that is acceptable (considering economic, energy and non-air impacts) will be evaluated by NDDH for visibility impact reduction. The results of conducting the first four step analysis will provide a recommendation to NDDH of a potential RHCT and the associated emission rate.

This analysis used several reference works, including the RACT/BACT/LAER Clearinghouse (RBLC), to identify which control technologies to evaluate. The technologies were reviewed for feasibility and those deemed infeasible were eliminated from further study. The feasible control technologies were ranked by control efficiency and estimates of costs to implement, operate, and maintain such technologies were developed for the top ranked technologies. Evaluating the top ranked technology based upon the average cost (dollars per ton removed) and other impacts determined if the top ranked technology was acceptable. The final RHCT results are summarized in the tables below. The RHCT emission rates are presented as a 30-day rolling average to account for variations in boiler operation and variations in fuel quality (including sulfur content).

MRYS Unit 1 RHCT 30-Day Rolling Average

Pollutant	Control Technology	Emission Rate (lb/million Btu)
NO _x	Existing Selective Non-Catalytic Reduction (SNCR) and Advanced Separated Over Fire Air (ASOFA) ¹	0.36
SO ₂	Modify the existing Wet Flue Gas Desulfurization (FGD) system ²	0.10

1: Excludes startups. See referenced BACT analysis for a detailed discussion.

MRYS Unit 2 RHCT 30-Day Rolling Average

Pollutant	Control Technology	Emission Rate (lb/million Btu)
NO _x	Existing Selective Non-Catalytic Reduction (SNCR) and Advanced Separated Over Fire Air (ASOFA) ¹	0.35
SO ₂	Modify the existing Wet Flue Gas Desulfurization (FGD) system ²	0.10

1: Excludes startups. See referenced BACT analysis for a detailed discussion.

The four factor analysis was completed based on a request by the North Dakota Department of Health (NDDH) while utilizing the EPA 2016 Guidance document. The NDDH has requested this information for the purpose of WRAP modeling. As EPA has indicated, the Regional Haze Roadmap may be updated, and the results of the WRAP modeling will provide new information to be considered, Minnkota reserves the right to modify the 4 Factor analysis once the Regional Haze Roadmap, any additional

guidance and the results of the WRAP modeling are available. In addition, Minnkota reserves the right to conduct a 5th Factor based on visibility modeling once the results of the WRAP modeling are available. This analysis is provided to assist the NDDH in the WRAP modeling and is not intended to serve as an agreement by Minnkota to any changes in permitted emission limits or permit conditions.

1.0 INTRODUCTION

The United States Environmental Protection Agency (U.S. EPA or EPA) finalized the Regional Haze Regulations (RHR) and Guidelines for Best Available Retrofit Technology (BART) Determinations¹ in the Federal Register on July 6, 2005 (70 FR 39104). In July, 2016, the EPA issued draft guidance for the second implementation period of the regional haze regulations². The draft guidance for the second implementation period retains many aspects of the BART guidelines.

The guidance documents, in general, indicate the goal of the second implementation period is to look at all sources for incremental visibility improvement including all sources that were previously Best Available Retrofit Technologies (BART) eligible. Milton R. Young Station Unit 1 and Unit 2 were previously determined to be BART-eligible by the NDDH. BART is defined as “an emission limitation based on the degree of reduction achievable through the application of the best system of continuous emission reduction for each pollutant which is emitted by a BART-eligible source. The emission limitation must be established on a case-by-case basis, taking into consideration the technology available, the costs of compliance, the energy and non-air quality environmental impacts of compliance, any pollution control equipment in use at the source, the remaining useful life of the source, and the degree of improvement in visibility which may reasonably be anticipated to result from the use of such technology” (70 FR 39163). Note that for MRYS, Minnkota has determined that the “remaining useful life of the source” is not a relevant factor in the analysis.

The second implementation guidance indicates a similar review to BART should be performed but in the second round the technology evaluation should be based on a ‘top down’ approach. The evaluation criteria are the same as the previous BART analysis; case-by-case basis considering availability, cost, energy and non-air quality impacts. However, in a ‘top down’ analysis the highest ranked technology that meets the acceptable criteria in the first four steps is the selected technology. The final determination of what top ranked technologies across the utility fleet will be accepted, if any, as RHCT is dependent on Step 5 (visibility modeling) and will be based on the modeling performed by the Western Regional Air Partnership (WRAP). This RHCT evaluation will be used by the NDDH as a tool to evaluate the potential to reduce emissions at Minnkota Power Cooperative, Inc.’s (Minnkota’s) Unit 1 and Square

Butte Electric Cooperative's (Square Butte's) Unit 2 at the Milton R. Young Station (MRYS) located near Center, North Dakota and the cost associated with these reductions.

1.1 RCHT Analysis Process

The general steps for determining RHCT for each pollutant are virtually the same as the previous BART steps (70 FR 39164) and are as follows:

STEP 1 - Identify all available retrofit control technologies.

STEP 2 - Eliminate technically infeasible options.

STEP 3 - Evaluate control effectiveness of remaining control technologies.

STEP 4 - Evaluate the following impacts for each feasible control technology and document results:

The cost of compliance.

The time required for compliance.

The energy and non-air quality environmental impacts of compliance.

The remaining useful life of the source.

STEP 5 – Evaluate the visibility impacts.

Unlike the previous BART analysis where all five steps were performed at once, NDDH's approach for the second implementation of the regional haze program is breaking the first four steps apart from the fifth step. The first four steps are performed on a 'top down' basis to determine the top ranked control technology that is applicable to each source. The fifth step is then taken by NDDH to determine which of the sources top down technologies are selected as RHCT.

Minnkota Power Cooperative, Inc. retained Burns & McDonnell to assist in the completion of the first four steps of the RHCT analysis for Milton R. Young Station. Burns & McDonnell is a full service engineering, architectural, construction and environmental firm. The company plans, designs and constructs electric generating facilities and has been providing environmental services to the power industry since the 1970s. As a result of their long history providing these services, Burns & McDonnell has extensive experience in permitting, Best Available Control Technology (BACT) studies, BART studies and control technology analysis similar to a RHCT analysis.

1.1.1 Identification of Retrofit Control Technologies

The initial step in the RHCT determination is the identification of retrofit control technologies. In order to identify the applicable control technologies, several reference works are consulted. A preliminary list of control technologies and their estimated capabilities is developed.

1.1.2 Feasibility Analysis

The second step of the RHCT process is to evaluate the control processes that have been identified and determine if any of the processes are technically infeasible. The BART guidelines are also applicable for the RHCT analysis and discuss consideration of two key concepts during this step in the analysis. The two concepts to consider are the “availability” and “applicability” of each control technology.

A control technology is considered available, “if the source owner may obtain it through commercial channels, or it is otherwise available in the common sense meaning of the term” or “if it has reached the stage of licensing and commercial availability.” On the contrary, a control technology is not considered available, “in the pilot scale testing stages of development.” (70 FR 39165) When considering a source’s applicability, technical judgment must be exercised to determine “if it can reasonably be installed and operated on the source type.” The EPA also does not “expect a source owner to conduct extended trials to learn how to apply a technology on a totally new and dissimilar source type.” (70 FR 39165) “A technology that is available and applicable is technically feasible.” (70 FR 39165)

1.1.3 Evaluate Technically Feasible Control Option by Effectiveness

The third step in the RHCT analysis is to evaluate the control effectiveness of the technically feasible alternatives. During the feasibility determination in step 2 of the analysis, the control efficiency is reviewed and presented with the description of each technology. The evaluation of the technically feasible alternatives concludes with the alternatives ranked in descending order of control effectiveness.

1.1.4 Impact Analysis

Step four in the analysis procedure is the impact analysis. The BART Determination Guidelines (70 FR 39166) and the draft guidelines for the second implementation period (81 FR 44608) each list four factors to be considered in the impact analysis. The RHCT evaluation will consider the following four factors in the impact analysis:

- The costs of compliance
- The time required for compliance
- The energy and non-air quality environmental impacts of compliance
- The remaining useful life of the source.

The first three of the four factors considered in the impact analysis are discussed in the associated pollutant section. The remaining useful life of the source is included as part of the cost of compliance.

In the second implementation period the impact analysis is performed on a 'top down' basis. The highest ranked (lowest emitting) technology is evaluated on the above factors for acceptability. If the top-ranked control technology is unacceptable, then the next highest ranked control technology is evaluated. This process continues until the highest ranked acceptable technology is identified.

1.1.5 Baseline Emissions

The cost of compliance evaluation is typically performed on a levelized dollars per tons of pollutant removed basis. In determining the tons removed, a baseline emission rate must be determined. The MRYS units both have existing SO₂ and NO_x pollution control systems that are part of the baseline. The baseline emission rate was developed by evaluating the 2014-2018 daily emissions data. A 30-day rolling average emission rate for all boiler operating days was developed and the highest 30-day value was determined. The highest 30-day emission rate for Unit 1 was 0.35 lbs/MMBtu NO_x and 0.14 lbs/MMBtu SO₂. The highest 30-day emission rate for Unit 2 was 0.35 lbs/MMBtu NO_x and 0.15 lbs/MMBtu SO₂. The highest 30-day rate is selected to reflect an emission rate the existing system would have maintained on a continuous basis during 2014-2018. Potential reductions from higher removal options will be evaluated from this baseline rate to evaluate the average/actual and incremental cost of control.

1.1.6 Methodology for Estimated Costs

The cost summary of each alternative is presented in the section for each pollutant. Installed capital and annual O&M cost estimates for each alternative are presented individually. The Levelized Total Annual Cost (LTAC) represents the levelized annual cost of procurement, construction and operation over a 20 year design life, in 2021 dollars. The LTAC represents an annual payment in current day dollars sufficient to finance the project over its entire life.

In determining the LTAC, a Capital Recovery Factor was calculated from the project economic conditions and then applied separately to the estimated capital costs. The equation used is shown below.

$$LACC / NPV = \left(\frac{i_d (1 + i_d)^n}{(1 + i_d)^n - 1} \right) = CRF$$

Where,

LACC = Levelized Annual Capital Cost

NPV = Net Present Value of the capital investments required.

i_d = discount rate

n = design life in years

CRF = Capital Recovery Factor

Therefore:

$$\text{LACC} = \text{CRF} \times \text{NPV}$$

For the economic conditions described in Table 1-1, the Capital Recovery Factor was calculated to be 0.08368.

The O&M cost used is the first year costs, in 2021 dollars. The O&M cost was not further inflated or otherwise levelized.

The Levelized Total Annual Cost, or LTAC is the sum of the levelized capital cost and the first year O&M cost. Therefore:

$$\text{LTAC} = \text{LACC} + 1^{\text{st}} \text{ Year O\&M} = (\text{CRF} \times \text{NPV}) + 1^{\text{st}} \text{ Year O\&M} = 0.08368 \times \text{NPV} + 1^{\text{st}} \text{ Year O\&M}$$

The economic analyses presented in this report not only include the estimated capital and annual O&M costs for each top ranked control technology, but also the LTAC for economic comparison.

Table 1-1: Economic Factors

Factor	Value
Total Possible Operating Hours per Year	8,760
Plant Capacity Factor	85%
Amortization Life, Years	20
Allowance for Funds Used During Construction	Not Included
Property Taxes, Insurance, %	NA
Amortization Rate for APC Capital Costs	0%
Discount Rate	5.5%
Construction Cost Escalation	3%
Maintenance Material and Labor Cost, % of Direct Capital	3%
Non-Fuel O&M Escalation	1.5%
Fuel (coal and natural gas) Escalation	1.5%
Auxiliary Electric Power Cost, \$/MW-hr	\$52.28
Reverse Osmosis Water, \$/kgal	\$9.44
Condensate water, \$/kgal	\$10.30
Urea 70% Solution, \$/ton	\$438.14
Lime, \$/ton	\$200.77
FGD Byproduct Disposal, \$/ton	\$6.27

(1) All costs are in 2021 dollars unless noted otherwise.

1.2 RHCT Analysis Approach

The purpose of the Regional Haze Rule (RHR) is to address visibility impairment in mandatory Class 1 areas. Before the actual RHCT analysis can begin the approach used to conduct the analysis should be addressed. The following sections present specific subjects related to MRYS's background, which warrant mention due to their effects on the contents of the report.

1.2.1 Background

Minnkota Power Cooperative, Inc. operates the Milton R. Young Station near Center, North Dakota. MRYS is a steam electric generating plant with two units. Unit No. 1 is a Babcock & Wilcox (B&W) cyclone-type coal-fired boiler burning lignite coal, serving a turbine generator with a nameplate rating of 257 MW.³ Unit 1 employs advanced separated over fire air (ASOFA) and selective non-catalytic reduction (SNCR) for NO_x control achieving 59% NO_x reduction. Particulate control is provided by a Research-Cottrell Electrostatic Precipitator rated at approximately 99% control. Unit 1 has a wet scrubber provided by Marsulex Environmental Technologies achieving compliance with a 30-day rolling average 95% SO₂ removal efficiency and exhausts to a 544 foot tall stack.

Unit No. 2 is a B&W cyclone-fired unit burning lignite coal, with a turbine-generator nameplate rating of 477 MW.⁴ Unit 2 employs ASOFA and SNCR for NO_x control achieving 60% NO_x reduction. Particulate control for Unit 2 is provided by a Wheelabrator-Lurgi precipitator rated at approximately 99% control. Unit 2 has a Combustion Equipment Associates wet flue gas desulfurization (FGD) system (modified by Combustion Engineering) achieving compliance with a 30-day rolling average 90% SO₂ removal efficiency and a 30-day rolling average 0.15 lb/MMBtu emission rate, and exhausts to a 550 foot tall stack.

Unit 1 began commercial operation on November 20, 1970 and Unit 2 on May 11, 1977.

³ "Generator Nameplate Data"; Emissions & Generation Resource Integrated Database (eGRID); U.S. Environmental Protection Agency; April, 2003.

⁴ Ibid footnote 3 reference.

2.0 NO_x RHCT EVALUATION

The RHCT analyses for NO_x emissions from MRYS Unit 1 and Unit 2 are described in this section. Technical descriptions of MRYS Unit 1 and Unit 2 boilers and existing air pollution control equipment are provided. Minnkota previously entered into a Consent Decree (CD) that required MRYS to install BACT for NO_x, which was determined to be Selective Non-Catalytic Reduction (SNCR) systems with Advanced Separated Overfire Air (ASOFA) on both units. These technologies are the current baseline condition for the two units.

2.1 NO_x Evaluation Basis

Milton R. Young Station Unit 1 includes a B&W steam generator installed in 1970. The steam generator is a lignite-fired boiler with multiple cyclone-furnaces installed in parallel using balanced-draft and natural circulation. Original unit design steam generating capacity is 1.714 million lbs/hr at 1,920 psi with a fuel heat input of 2,510 MMBtu/hr. The boiler is fired by seven ten-foot diameter cyclone burners, arranged “three over four” across the front wall of the lower furnace. The unit has a tubular air heater installed between the boiler and the flue gas ductwork leading to the electrostatic precipitator (ESP). Unit 1’s boiler serves a turbine generator with a nameplate rating of 257 MW⁵. The Unit 1 boiler at MRYS includes a unique coal conditioning system (drying, crushing, and feeding) for each cyclone furnace specifically designed to aid in proper combustion of the lignite fuel. Lignite fuel is the sole solid fuel for the plant and is supplied from a mine located adjacent to the site.

Milton R. Young Unit 2 is a B&W steam generator installed in 1977. The steam generator is a lignite-fired boiler with multiple cyclone-furnaces installed in parallel using balanced-draft and natural circulation assisted with circulation pumps. Original unit design steam generating capacity is 3.20 million lbs/hr at 2,620 psi with a fuel heat input of 4,696 MMBtu/hr. The boiler is fired by twelve ten-foot diameter cyclone burners, arranged “three over three” across the front and rear walls of the lower furnace. The unit has a tubular air heater installed between the boiler and the flue gas ductwork leading to the ESP. Unit 2’s boiler serves a turbine-generator with a nameplate rating of 477 MW⁶. The Unit 2 boiler at MRYS includes a unique coal conditioning system (drying, crushing, and feeding) for each cyclone furnace specifically designed to aid in proper combustion of the lignite fuel. Lignite fuel is the sole solid fuel for the plant and is supplied from a mine located adjacent to the site.

⁵ Ibid EPA’s eGRID database; April, 2003.

⁶ Ibid EPA’s eGRID database; April, 2003.

2.2 Identification of Retrofit NOx Control Technologies

The initial step in the RHCT determination is the identification of retrofit NOx control technologies. In order to identify the applicable NOx control technologies, several reference works were consulted, including the RACT/BACT/LAER Clearinghouse (RLBC). From this and other literature sources, a preliminary list of control technologies and their estimated capabilities for potential application to MRYS was developed. However, as discussed in the introduction, Minnkota already has ASOFA and SNCR systems installed on both units to achieve 30-day rolling average removal rates of approximately 60% on Unit 1 and Unit 2. Thus, the control technologies included in the RHCT analysis either meet this minimum level of control or have more stringent removal efficiency. Table 2-1 contains the results of this effort.

Table 2-1: NOx Control Technologies Identified for RHCT Analysis

Control Technology	Approximate Control Efficiency*
Selective Catalytic Reduction and Advanced Separated Over Fire Air (ASOFA)	90%
Rich Reagent Injection and Selective Non-Catalytic Reduction and Advanced Separated Over Fire Air (ASOFA)	66-67%
Optimized Selective Non-Catalytic Reduction and Advanced Separated Over Fire Air (ASOFA)	61-62%
Existing Selective Non-Catalytic Reduction* and Advanced Separated Over Fire Air (ASOFA)	Baseline 59-60%

*Based on pre SNCR/ASOFA baseline of 0.884/0.874 lb NOx/MMBtu for Units 1 and 2, respectively.

2.3 Technical Description and Feasibility Analysis

The second step in the RHCT analysis procedure is a technical feasibility analysis of the options identified in Step 1. The RHCT guidelines discuss consideration of two key concepts during this step in the analysis. The two concepts to consider are the “availability” and “applicability” of each control technology. A control technology is considered available, “if it has reached the stage of licensing and commercial availability.” (70 FR 39165) On the contrary, a control technology is not considered available, “if it is in the pilot scale testing stages of development.” (70 FR 39165) When considering a source’s applicability, technical judgment must be exercised to determine “if it can reasonably be installed and operated on the source type.” (70 FR 39165) The technical and feasibility analysis is presented below for each identified option.

2.3.1 Selective Catalytic Reduction

The lowest NOx emission levels from coal-fired utility boilers are typically achieved by installing and operating selective catalytic reduction (SCR) technology. In the SCR process, the gas stream is passed through a catalyst bed in the presence of ammonia to reduce NOx to molecular nitrogen and water. The

process is termed “selective” because the ammonia preferentially reacts with the NO_x rather than with the oxygen in the flue gas. A large reactor containing catalyst is used to enhance NO_x reduction and ammonia utilization at lower flue gas temperatures than required by a SNCR system. SCR is usually applied to flue gas in the 600°F to 750°F temperature range. There are variations in the SCR process for coal-fired boilers that mostly involve locations in the flue gas path where the catalyst is placed in order to promote the desired NO_x emission reduction effect. This technology was reviewed in the previous BART and BACT analysis (2008-2010) and it was concluded by NDDH that SCR systems (of all types) are not technically feasible at the Milton R Young facility. No new information or experience has occurred since 2010 to change the result of this analysis and this technology remains not technically feasible.

2.3.2 Rich Reagent Injection & Selective Non-Catalytic Reduction

Rich Reagent Injection (RRI) has been demonstrated and placed in continuous operation on multiple cyclone-fired boilers. RRI is specifically intended for NO_x emissions control on cyclone boilers. RRI adds dilute urea reagent to the hot furnace gases near the cyclones, which must be devoid of free oxygen in order to avoid oxidation of the urea. This system is combined with a SNCR system to further reduce NO_x emissions within the boiler. However, the RRI injection location is limited to the lower portion of the furnace and requires an oxygen deprived environment. RRI is considered technically feasible for application on the Unit 1 and Unit 2 cyclone boilers at the Milton R. Young Station.

2.3.3 Optimized Selective Non-Catalytic Reduction

Taking into consideration the past operating experience of the existing system and vendor experience since the original installation, there is potential to reduce the emission rate further with enhancements to the existing design. These enhancements could include changing the nozzles on existing lances, replacing the existing lances, and adding lances in new locations. Additionally, allowing for higher ammonia slip rates than originally designed will allow for higher levels of urea injection which has the potential to further reduce NO_x emission rates. Optimized SNCR is considered technically feasible for application on the Unit 1 and Unit 2 cyclone boilers at the Milton R. Young Station.

2.3.4 Results of Feasibility Analysis

The evaluations of the identified RHCT alternatives following the feasibility analysis are summarized in Table 2-2.

Table 2-2: MRYS RHCT NOx Control Feasibility Analysis Results

Control Technology	In full-scale service on Existing Utility Boilers	In Service on Other Combustion Sources	Commercially Available	Technically Applicable To Milton R. Young Station
SCR	Yes	Yes	No*	No
RRI + SNCR	Yes	Yes	Yes	Yes
Optimized SNCR	Yes	Yes	Yes	Yes
Existing SNCR	Yes	Yes	Yes	Yes

*Not available on cyclone fired units firing North Dakota lignite.

2.4 Evaluate the Technically Feasible NOx Control Options by Effectiveness

The third step in the RHCT analysis procedure is to evaluate the control effectiveness of the technically feasible alternatives. During the feasibility determination in step 2 of the RHCT analysis, the NOx control efficiency was reviewed and presented as part of the technical description for each technology. The evaluations of the remaining RHCT alternatives following the feasibility analysis are summarized in Table 2-3. The alternatives are ranked in 'top down' descending order according to their effectiveness in NOx control.

Table 2-3: Feasible NOx Control Technologies Identified for RHCT Analysis

Control Technology	Unit 1 lb/MMBtu	Unit 2 lb/MMBtu
RRI + SNCR	0.30	0.29
Optimized SNCR	0.345	0.335
Existing SNCR	0.36	0.35

The emission rates identified above were developed as continuously achievable 30-day emission rates taking into account vendor supplied information, variations in load, experience in the long-term variation of boiler NOx control technologies, and the variable quality associated with the supply of mine mouth lignite. The vendor information is based on MRYS unit-specific boiler mapping data and CFD modeling results to determine the equipment, approximate injection locations, and subsequent emission rate. The emission rates take into account that the rates must be continuously achievable on a 30-day period including the impacts of changing unit loads, control equipment limitations, and variability in coal quality.

Load variations must be considered because at lower loads the ability to control NOx is reduced. The RRI and SNCR systems are designed to inject dilute ammonia/urea into the correct temperature zones in the boiler for NOx control. The maximum NOx reductions from both RRI and SNCR systems occur when the boiler is at or near full load. At other conditions the ability to control NOx can be significantly impacted. RRI operation depends on oxygen-deprived conditions, and without this (such as with a single

cyclone out of service and/or at lower loads), using the RRI system could increase NOx emissions. Multiple levels of injection are included to introduce reagent into the correct temperature zone at multiple loads. However, even with multiple injection levels, emission reductions are reduced at lower loads.

The Milton R. Young facility is a mine-mouth plant that utilizes run-of-mine fuel, resulting in significant coal quality variability. Within a 30-day period, the plant can, and has, experienced multiple days of lower quality coal that in turn, creates conditions that make NOx harder to control (such as burning fuel oil to control cyclone fouling), increasing emissions and reagent usage rates.

These factors, along with unit-specific vendor information, were considered in developing the continuously achievable 30-day emission rates. The emission rates guaranteed by vendors are based on stable, steady state operating conditions, and do not reflect the varying conditions that occur over the life of the equipment or even in a 30-day operating period. A 30-day emission rate must account for operating during periods such as the transition period between two planned stable load conditions, and other unplanned operating variations such as changing coal quality.

2.5 Evaluation of Impacts for Feasible NOx Controls

Step four in the RHCT analysis procedure is the impact analysis. The draft Guidelines (81 FR 44608) lists four factors to be considered in the impact analysis.

- The costs of compliance
- The time required for compliance
- The energy and non-air quality environmental impacts of compliance
- The remaining useful life of the source

Three of the four impacts required by the RHCT Guidelines are discussed in the following sections. The remaining useful life of the source was determined to be greater than the project life definition in the EPA's OAQPS Control Cost Manual (EPA/453/B-96-001) and thus had no impact on the RHCT determination for MRYS.

2.5.1 Cost Estimates

Cost estimates for the RRI + SNCR control technology were developed based on vendor budgetary quotes, and installation estimates were based upon Burns & McDonnell's in-house experience. The vendor has utilized MRYS unit-specific boiler mapping data and CFD modeling results to determine the

equipment and approximate injection locations. Economic information utilized as inputs to the model are provided in Table 1-1.

2.5.1.1 RRI + SNCR Capital Cost Estimate

The vendor equipment cost estimate for the RRI and SNCR system includes new RRI injectors for the lowest level of the boiler, a new RRI distribution module, and modifications to the existing SNCR system to provide load-following flexibility. The remaining capital cost estimate includes installation of the vendor equipment, supply and installation of necessary equipment access, and balance of plant (BOP) costs. The NOx control system cost is representative of a typical furnish and erect contract.

Table 2-4: Capital Cost Estimate for MRYS Unit 1 & 2 RRI + SNCR System

DIRECT COSTS	Unit 1 Estimated Cost (\$)	Unit 2 Estimated Cost (\$)
RRI and SNCR System		
Equipment Cost	\$4,283,000	\$5,507,000
BOP Costs		
Mechanical Contract	\$1,611,000	\$4,709,000
Foundations and Steel	\$559,000	\$900,000
Electrical and Controls	\$131,000	\$179,000
BOP Total Direct Cost =	\$2,301,000	\$5,788,000
Total Direct Cost =	\$6,584,000	\$11,295,000
INDIRECT COSTS		
Engineering 10% of DC	\$647,000	\$1,129,000
Escalation to 2021	\$611,000	\$1,048,000
Indirect Cost Subtotal	\$1,258,000	\$2,177,000
Contingency (20% of DC)	\$784,000	\$1,348,000
Prime Contractor's Fee (3% of DC)	\$604,000	\$1,038,000
Total Capital Requirement	\$9,230,000	\$15,858,000

The total estimated capital cost estimate to upgrade the existing Unit 1 SNCR system to a RRI + SNCR system is \$9,230,000, or \$35.9/kW. The total estimated capital cost estimate to upgrade the existing Unit 2 SNCR system to a RRI + SNCR system is \$15,858,000, or \$33.2/kW.

2.5.1.2 Optimized SNCR Capital Cost Estimate

The vendor equipment cost estimate for optimizing the SNCR system is based on vendor estimates and may include changing the nozzles on the existing lances, replacing the existing lances, adding lances in new locations, and/or boiler modifications for the additional lances. The NOx control system cost is representative of a typical furnish and erect contract.

Table 2-5: Capital Cost Estimate for MRYS Unit 1 & 2 Optimized SNCR System

DIRECT COSTS	Unit 1 Estimated Cost (\$)	Unit 2 Estimated Cost (\$)
Optimized SNCR System		
SNCR Equipment Cost	\$628,000	\$748,000
BOP Costs		
Mechanical Contract	\$311,000	\$932,000
Foundations and Steel	\$100,000	\$250,000
Electrical and Controls	\$15,000	\$25,000
BOP Total Direct Cost =	\$425,000	\$1,207,000
Total Direct Cost =	\$1,054,000	\$1,955,000
INDIRECT COSTS		
Engineering 10% of DC	\$105,000	\$195,000
Escalation to 2021	\$98,000	\$181,000
Indirect Cost Subtotal	\$203,000	\$376,000
Contingency (20% of DC)	\$126,000	\$233,000
Prime Contractor's Fee (3% of DC)	\$97,000	\$180,000
Total Capital Requirement	\$1,479,000	\$2,744,000

The total estimated capital cost estimate to optimize the Unit 1 SNCR system is \$1,479,000 or \$5.8/kW.

The total estimated capital cost estimate to optimize the Unit 2 SNCR system is \$2,744,000, or \$5.8/kW.

2.5.1.3 RRI + SNCR O&M Cost Estimate

The annual operating and maintenance costs (O&M) costs are comprised of fixed costs (maintenance and labor) and variable cost (consumables). The fixed costs include operating labor, administrative and support labor and the maintenance material and labor costs. No change in administrative, support and operating labor cost was assumed. The maintenance material and labor cost was estimated at

approximately 3% of the system direct capital cost in Table 2-4. Table 2-6 summarizes the O&M cost estimates for the RRI + SNCR system.

Variable costs include reagent, cooling water, auxiliary power costs and increased coal consumption. The estimated annual costs for these consumables are the estimated change from the baseline conditions based on vendor provided consumption rates, unit operating assumptions and the unit cost information provided in Table 1-1. The coal consumption cost increases because of the significant quantity of water that is introduced to the boiler with increased dilute urea injection. This additional water is evaporated and negatively impacts the unit efficiency.

Table 2-6: O&M Cost Estimate for MRYS Unit 1 & 2 RRI + SNCR System

Fixed Costs	Unit 1	Unit 2
Operating Labor	\$0	\$0
Admin and Support labor	\$0	\$0
Maintenance Material and Labor	\$47,000	\$54,000
Total Fixed O&M Costs =	\$47,000	\$54,000
Variable Costs		
Dilute Urea Reagent	\$4,977,000	\$4,348,000
Water	\$296,000	\$696,000
Auxiliary Power	\$52,000	\$52,000
Increased Coal Usage	\$289,000	\$687,000
Total Variable O&M Costs =	\$5,614,000	\$5,783,000
Total Annual O&M Costs	\$5,661,000	\$5,837,000
Net Annual O&M Cost (\$/MWh)	2.96	1.64

O&M Cost represent costs above the baseline (existing system)

2.5.1.4 Optimized SNCR O&M Cost Estimate

The annual operating and maintenance costs (O&M) costs are comprised of fixed costs (maintenance and labor) and variable cost (consumables). The fixed costs include operating labor, administrative and support labor and the maintenance material and labor costs. The maintenance material and labor cost was estimated at approximately 3% of the new direct capital cost in Table 2-5. No change in administrative, support and operating labor cost was assumed. Table 2-7 summarizes the O&M cost estimates for the RRI + SNCR system.

Variable costs include reagent, cooling water, auxiliary power costs and increased coal consumption. The estimated annual costs for these consumables are the estimated change from the baseline conditions based on vendor provided consumption rates, unit operating assumptions and the unit cost information provided in Table 1-1 Economic Design Criteria. The coal consumption cost increases because of the significant

quantity of water that is introduced to the boiler with increased dilute urea injection. This additional water is evaporated and impacts the unit efficiency.

Table 2-7: O&M Cost Estimate for MRYS Unit 1 & 2 Optimized SNCR System

Fixed Costs	Unit 1	Unit 2
Operating Labor	\$0	\$0
Admin and Support labor	\$0	\$0
Maintenance Material and Labor	\$19,000	\$22,000
Total Fixed O&M Costs =	\$19,000	\$22,000
Variable Costs		
Dilute Urea Reagent	\$1,820,000	\$717,000
Water	\$85,000	\$296,000
Auxiliary Power	\$26,000	\$26,000
Increased Coal Usage	\$57,000	\$253,000
Total Variable O&M Costs =	\$1,988,000	\$1,292,000
Total Annual O&M Costs	\$2,007,000	\$1,314,000
Net Annual O&M Cost (\$/MWh)	1.05	0.37

O&M Cost represent costs above the baseline (existing system)

2.5.1.5 Levelized Total Annual Cost

In order to effectively compare the cost of installing, operating and maintaining the NOx control systems, capital and O&M costs can be evaluated on a levelized basis.

The Levelized Total Annual Cost (LTAC) for NOx control systems was calculated based on a 20-year project life and are presented in Table 2-8 and Table 2-9 along with the emissions reduction, resultant emissions rate and the Unit Control Cost. No salvage value was assumed at the end of the service life. The Unit Control Cost is the LTAC divided by the annual tons of NOx emissions that would be controlled by implementation of the respective alternative. The Levelized Total Annual Cost and Unit Control Cost are used to evaluate the technology alternatives on a cost effectiveness basis.

Table 2-8: Levelized Total Annual Cost of MRYS Unit 1 NOx Control Technologies

NO _x Control Alternative	Emission Rate lb/10 ⁶ Btu	Annual Emissions (tpy) ¹	Annual Emission Reduction (tpy) ¹	Installed Capital Cost (\$2021) ²	Annual O&M Cost (\$2021)	Levelized Total Annual Cost (\$2021) ³	Actual Unit Control Cost (\$/ton) ⁴	Incremental Unit Control Cost (\$/ton)
RRI+SNCR/ASOFA	0.30	2,803	467	9,230,000	5,661,000	6,433,360	13,769	10,232
Optimized SNCR/ASOFA	0.345	3,224	47	1,479,000	2,007,000	2,130,762	45,603	
Existing SNCR/ASOFA ⁵	0.35	3,271	Baseline					

1. Based on 2,510 MMBtu/hr and 85% capacity factor.
2. All Costs in 2021 dollars.
3. For LTAC calculation, Capital Recovery Factor = 0.08368 and first year O&M Cost.
4. Overall control cost is LTAC divided by actual annual emissions reduction of each alternative.
5. Baseline emission rate based on maximum 30-day emission rate between 2014-2018.

Table 2-9: Levelized Total Annual Cost of MRYS Unit 2 NOx Control Technologies

NO _x Control Alternative	Emission Rate lb/10 ⁶ Btu	Annual Emissions (tpy) ¹	Annual Emission Reduction (tpy) ¹	Installed Capital Cost (\$2021) ²	Annual O&M Cost (\$2021)	Levelized Total Annual Cost (\$2021) ³	Actual Unit Control Cost (\$/ton) ⁴	Incremental Unit Control Cost (\$/ton)
RRI+SNCR/ASOFA	0.29	5,070	1049	15,858,000	5,837,000	7,163,987	6,829	7,144
Optimized SNCR/ASOFA	0.335	5,857	262	2,744,000	1,314,000	1,543,644	5,886	
Existing SNCR/ASOFA ⁵	0.35	6,119	Baseline					

1. Based on 4,696 MMBtu/hr and 85% capacity factor.
2. All Costs in 2021 dollars.
3. For LTAC calculation, Capital Recovery Factor = 0.08368 and first year O&M Cost.
4. Overall control cost is LTAC divided by actual annual emissions reduction of each alternative.
5. Baseline emission rate based on maximum 30-day emission rate between 2014-2018.

2.5.1.6 Cost Estimate Conclusion

In the RHCT guidelines, EPA does not provide definition, or even discussion of what Unit Control Costs are considered reasonable or unreasonable. NDDH has indicated that costs below \$5,000 per ton may be considered to be reasonable.

The cost analysis portion of the RHCT determination for MRYS Unit 1 and 2 indicates that Actual Unit Control Costs for the top ranked RRI + SNCR for Unit 1 is more than double \$5,000 per ton and the Unit 2 cost is well above \$5,000 per ton. The incremental rate (cost of removal between two options) of controlling NO_x with RRI + SNCR is also over \$5,000 per ton on both Units. From an economic analysis

viewpoint, the RRI+SNCR system, although the top ranked technology, is not an economically effective NOx control alternative for either Unit 1 or Unit 2.

The Actual Unit Control Costs for the next top ranked control technology, optimized SNCR system, is above \$5,000 per ton on Unit 1 and Unit 2. From an economic analysis viewpoint, optimized SNCR system is not an economically effective NOx control alternative for Unit 1 or Unit 2.

2.5.2 Energy Impacts

The primary energy impact of the RRI + SNCR and Optimized SNCR systems is reduced boiler efficiency due to evaporation of large amounts of dilute urea. For Unit 1, the equivalent of an additional 39 tons of coal per day will be required to evaporate the expected amount of dilute urea to be injected into the boiler. For Unit 2, the equivalent of an additional 93 tons of coal per day will be required to evaporate the expected amount of dilute urea to be injected into the boiler. Increasing heat input to maintain present unit production capacity may have PSD implications that could add significant cost and significant permitting considerations.

Other energy impacts include an incremental increase in water consumption due to the need for additional cooling water, and an incremental increase in energy related to providing more compressed air for reagent atomization. The impact of these items is negligible.

Table 2-10: Energy Requirement of MRYS Unit 1 NOx Control Technologies

RHCT Alternative	Energy Demand (kW)	Percent of Nominal Generation
Existing SNCR	200	0.09%
Optimized SNCR	266	0.11%
RRI + SNCR	332	0.14%

Table 2-11: Energy Requirement of MRYS Unit 2 NOx Control Technologies

RHCT Alternative	Energy Demand (kW)	Percent of Nominal Generation
Existing SNCR	300	0.07%
Optimized SNCR	366	0.08%
RRI + SNCR	432	0.10%

2.5.3 Non-Air Quality Environmental Impacts

The addition of the RRI system to the SNCR system is not expected to significantly impact emissions of CO or volatile organic compounds (VOCs).

Operation of the existing SNCR-related system creates a small amount of unreacted ammonia to be emitted. In the future, the settings for the new RRI+SNCR or Optimized SNCR system may increase the amount of ammonia slip produced. Higher NO_x reduction performance involves greater amounts of reagent usage and consequently, the increased ammonia slip. This is typically controlled to less than 10 ppmvd, especially when the possible formation of sulfates such as ammonium sulfate [(NH₄)₂SO₄] and ammonium bisulfate [NH₄HSO₄] will be more problematic at higher slip levels. Sulfur trioxide (SO₃) formed during combustion in the boiler can combine with ammonia during passage through the flue gas ductwork to form the sulfates.

Some of the unreacted ammonia (ammonia slip) will be collected with the flyash in the ESP. Any remaining ammonia slip that is not collected or condensed in the air pollution control system will be collected in the wet scrubber or emitted from the stack as an aerosol or condensable particulate.

Increasing the ammonia slip has the potential to increase atmospheric visibility impairment downwind of the facility compared with a pristine condition. Although the predicted amount of such potential impact from ammonia slip emissions has not been determined, it is expected to be small in comparison with the significant anticipated reduction in far-field ozone and improvement in atmospheric visibility as a result of the overall NO_x emission reduction.

One mole of carbon dioxide (CO₂) will be created and emitted for every mole of urea injected for reaction with NO_x. The consumption rate of urea will significantly increase with the use of RRI+SNCR or optimized SNCR and thus the CO₂ rate will also increase. However, this is a relatively small increase in the total amount of CO₂ produced as part of the combustion of carbon-based fossil fuel in the form of lignite.

Delivery of the urea reagent to the MRYS and storage of aqueous urea reagent on-site creates the potential for accidents, leaks, and subsequent releases to air, ground, and surface water immediately surrounding the facility. Urea is much less volatile than anhydrous or aqueous ammonia, and these risks are expected to be manageable. Emergency planning and community communications are already part of the management plan requirements for such reagent usage.

Increased dilution water and urea usage rates will require the production of greater volumes of Reverse Osmosis (RO)/condensate quality water for dilution of concentrated urea deliveries and injection into the boiler. The production of RO/condensate quality water results in a discharge of a concentrated brine solution, which is ultimately discharged under the requirements of the facility NDPDES permit. This waste stream typically represents 20% of the RO product volume produced. This would result in millions of gallons of additional water treatment wastewaters being discharged from the MRYS facility on an annual basis.

3.0 SO₂ RHCT EVALUATION

The RHCT determination process has five predefined steps as described in Section 1. In this section, steps 1 through 4 of the RHCT determination for Milton R. Young Station (MRYS) are described for SO₂ and a presentation is made of the results. Potentially applicable SO₂ control technologies are first identified. A brief description of the processes and their capabilities are reviewed for availability and feasibility. Subsequently, those available technologies deemed feasible for retrofit application are ranked according to nominal SO₂ control capability. The impacts analysis then reviews the estimated capital and O&M costs for each alternative. Following the cost determination, the energy impacts and non-air quality impacts are reviewed for each technology. The impact based on the remaining useful life of the source is reviewed as part of the cost analysis. The results of the impact analyses are tabulated and potential RHCT options are listed.

3.1 Identification of Retrofit SO₂ Control Technologies

The initial step in the RHCT determination is the identification of retrofit SO₂ control technologies. In order to identify the applicable SO₂ control technologies, several reference works were consulted, including "Controlling SO₂ Emissions: A Review of Technologies (EPA-600/R-00-093, October 2000) and the RACT/BACT/LAER Clearinghouse (RLBC). From these and other literature sources, a preliminary list of control technologies and their estimated capabilities for potential application to MRYS was developed. However, Minnkota already has wet FGD systems installed on both units to achieve 30-day rolling average removal rates of 95% and 90% on Unit 1 and 2, respectively. Additionally, Unit 2 complies with a 0.15 lb/MMBtu 30-day rolling average emission rate. Thus, the control technologies included in the RHCT analysis either meet this minimum level of control or have more stringent removal efficiency. Table 3-1 contains the results of this effort.

Table 3-1: SO₂ Control Technologies Identified for RHCT Analysis

Control Technology	Approximate Control Efficiency
ReACT Scrubber	92-98%
New Wet Flue Gas Desulfurization (FGD)	98%
Modify Existing Wet FGD	96-97%
Circulating Semi-Dry FGD	90-97%
Semi-Dry FGD	90-95%

3.2 Technical Description and Feasibility Analysis

The second step in the RHCT analysis procedure is a technical feasibility analysis of the options identified in Step 1. The RHCT guidelines, which reference the prior BART Guidelines, discuss consideration of two key concepts during this step in the analysis. The two concepts to consider are the “availability” and “applicability” of each control technology. A control technology is considered available “if it has reached the stage of licensing and commercial availability” (70 FR 39165). On the contrary, a control technology is not considered available “if it is in the pilot scale testing stages of development” (70 FR 39165). When considering a source’s applicability, technical judgment must be exercised to determine “if it can reasonably be installed and operated on the source type” (70 FR 39165). The technical and feasibility analysis is presented below for each identified option.

3.2.1 Wet Flue Gas Desulfurization

Wet FGD technology utilizing lime or limestone as the reagent is commonly applied to coal-fired boilers. Wet FGD utilizes an absorber, such as an open spray tower or a spray tower with a perforated plate contactor, to expose flue gas to the neutralizing slurry. Absorbed SO₂ is converted to calcium sulfite and then may be oxidized to calcium sulfate dihydrate (gypsum) which is filtered from the scrubber solution and either disposed of in a permitted disposal facility, or possibly sold for either wallboard or cement production. Lime is utilized as the reagent in the wet FGD technology analysis, because the plant currently uses lime in the FGD processes and has existing lime reagent preparation equipment. Lime, rather than limestone, is used at the plant because it is the most cost-effective reagent to truck to the plant. The MRYS is not equipped with rail service.

An alternative reagent to lime or limestone is ammonia. The scrubbing technology is similar to other wet FGD systems; however, the byproduct handling is significantly different. The advantage of utilizing ammonia is the production of a high value fertilizer byproduct (ammonium sulfate). This byproduct is a commodity that can be sold worldwide all year. The disadvantage of utilizing ammonia reagent is the byproduct requires significant handling/treatment. This handling/treatment includes concentration, crystallization, drying, prilling and storage. Because ammonium sulfate is highly soluble in water, landfilling the byproduct is not feasible so the product must be stored and sold. As fertilizer is generally seasonal demand in a given part of the country, therefore access to the world market is necessary.

Historically, wet FGD systems have operated with SO₂ control efficiency anywhere from 70% to 98%. New coal-fired power plant SO₂ control projects have achieved coal to stack SO₂ control efficiency of ≥99 percent. However, considering a reasonable degree of margin is appropriate to allow for continuous

compliance including upsets, fuel variability, and operational variability, 98% removal on a 30-day rolling average basis is considered an appropriate removal rate for a new state of the art scrubber.

For the purposes of this analysis, a new wet FGD performance was evaluated at 98% SO₂ removal. Due to the relative ages of Unit 1 and Unit 2 scrubbers, a new wet scrubber was considered only for Unit 2, as the Unit 1 wet scrubber was placed in service relatively recently, in 2011. Based on the ability of a new wet FGD system to achieve 98% percent SO₂ removal efficiency and considering the commercial availability and applicability, a new wet FGD system was found to be an acceptable RHCT alternative for MRYS Unit 2 SO₂ emission control.

This report also evaluates the modification of the existing wet FGD process currently operating on Unit 1 and Unit 2 as a possible RHCT alternative. The original equipment manufacturer (OEM) of the Unit 1 scrubber was engaged to evaluate modifications required to increase the removal efficiency of the existing wet FGD processes. The same OEM has previously studied upgrading the Unit 2 scrubber to achieve higher removal efficiency, and was engaged to update and confirm the results of that study. Through this evaluation it was determined modifications can be made to achieve 95-98% removal in each of the two existing scrubbing systems. Upgrades include increasing the liquid-to-gas ratio, installation of new types of spray nozzles, running additional pumps, and adjusting the operating conditions of the scrubber.

The range of removal is dependent on both mechanical upgrades and a range of potential chemistry changes. The potential operating condition changes were evaluated with the Owner's experience with these different operating conditions and considering the impacts they have on reliability and BOP impacts (scaling, nozzle plugging, byproduct settling/removal). Considering these potential impacts/risks, this evaluation assumes 97% removal from the maximum future sulfur fuel (3.2 lb SO₂/MMBtu) to set a not to exceed emission rate. Because the 10 year mining plan indicates the sulfur content of the coal will vary by 40% (generally increasing in the future) a minimum removal rate of 96% is also included.

3.2.2 Semi-Dry Flue Gas Desulfurization

As an alternative to wet FGD technology, the control of SO₂ emissions can be accomplished using semi-dry FGD technology. The most common semi-dry FGD system is the lime Spray Dryer Absorber (SDA) using a fabric filter for downstream particulate collection. There are several variations of the semi-dry process in use today. Two other variations, the Flash Dryer Absorber (FDA) and Circulating Dry Scrubber (CDS) are similar in nature. They primarily differ by the type of reactor vessel used, the method in which water and lime are introduced into the reactor and the degree of solids recycling. This section addresses the SDA process and the CDS process.

No SDA process has clearly demonstrated the ability to achieve SO₂ removal levels similar to wet FGD systems in the U.S. The application of high SO₂ removal SDA system for high sulfur coal have been limited in the industry due to multiple factors. For purposes of completeness an SDA system is assumed to be able to achieve 93% removal in this application.

The CDS system can increase the lime injection rate independent of the water injection, higher removal rates can be achieved. The CDS system removal is assumed to be equivalent to the retrofit wet FGD system achieving 95-97% removal.

3.2.3 ReACT Dry Scrubbing Process

ReACT (Regenerative Activated Coke Technology) is a multipollutant control system that utilizes activated coke to remove SO₂, NO_x and mercury. The process is divided into three main processes; 1) adsorption, 2) regeneration, 3) recovery. In the first step ammonia is injected into the flue gas and the flue gas is passed through an adsorber filled with a moving bed of activated coke pellets where the SO₂ and mercury are adsorbed and the NO_x is reduced to N₂. In the second step the activated coke pellets are transferred to a second vessel to be regenerated for recycle/reuse through thermal desorption. The captured mercury is concentrated in the lower portion of the regenerator vessel. The resulting gas from the regeneration step is a concentrated stream of SO₂ that must be further treated in a separate acid recovery plant to produce a sellable sulfuric acid byproduct. Sulfuric acid is a worldwide commodity that, with access, can be sold year-round. This ReACT process is installed and operating on multiple low sulfur coal fired units achieving ≥98% SO₂ removal. Burns & McDonnell contacted the supplier of the ReACT process and discussed the application of the technology to an application like MRYS. It was determined that MRYS is 'not a good application' for the technology, however, the technology could be applied and would work. Factors in this application at MRYS that would impact performance and cost of ReACT include that the inlet temperature is too high, higher oxidation of the activated coke can be expected, and the sulfuric acid production rates would be very high. This technology is still considered a viable alternative and previous ReACT pilot tests on high sulfur coals have shown ReACT can achieve 92-98% SO₂ removal rates.

3.2.4 Results of Feasibility Analysis

The evaluations of the identified RHCT alternatives following the feasibility analysis are summarized in Table 3-2.

Table 3-2: MRYS RHCT SO₂ Control Feasibility Analysis Results

Control Technology	In full-scale service on Existing Utility Boilers	In Service on Other Combustion Sources	Commercially Available	Technically Applicable To Milton R. Young Station
ReACT Scrubber	Yes	Yes	Yes	Yes
Wet FGD	Yes	Yes	Yes	Yes
CDS Dry FGD	Yes	Yes	Yes	Yes
SDA Dry FGD	Yes	Yes	Yes	Yes

3.3 Evaluate Technically Feasible SO₂ Control Options by Effectiveness

The third step in the RHCT analysis procedure is to evaluate the control effectiveness of the technically feasible alternatives. During the feasibility determination in step 2 of the RHCT analysis, the SO₂ control efficiency was reviewed and presented as part of the technical description for each technology. The evaluations of the remaining RHCT alternatives following the feasibility analysis are summarized in Table 3-3. The alternatives are ranked in descending order according to their effectiveness in SO₂ control.

Table 3-3: Feasible SO₂ Control Technologies Identified for RHCT Analysis

Control Technology	Unit 1	Unit 2
New Wet FGD	Not Reviewed*	98% Control
ReACT	98% Control	98% Control
Retrofit Existing Wet FGD	97% Control	97% Control
CDS Semi-Dry FGD	NA**	NA**
SDA FGD	NA**	NA**

*Existing system was installed in 2011, so replacement with a like-kind system was not reviewed.

**SDA semi-dry FGD is not evaluated for Unit 1 or 2 because the existing wet FGD can be used to achieve equivalent removal efficiency while using existing equipment.

3.4 Evaluation of Impacts for Feasible SO₂ Controls

Step four in the RHCT analysis procedure is the impact analysis. The draft Guidelines (81 FR 44608) lists four factors to be considered in the impact analysis.

- The costs of compliance;
- The time required for compliance;
- Energy and non-air quality environmental impacts of compliance; and
- The remaining useful life of the source.

Three of the four impacts required by the RHCT Guidelines are discussed in the following sections. The remaining useful life of the source was determined to be greater than the project life definition in the

EPA's OAQPS Control Cost Manual (EPA/453/B-96-001) and thus had no impact on the RHCT determination for MRYS.

Unlike the Best Available Retrofit Technology (BART) evaluation performed in the last round for the RHCT evaluation, the technologies in the second implementation period are evaluated on a 'Top Down' down basis similar to a Best Available Control Technology (BACT) approach. Where multiple technologies achieve similar removal rates, a single technology is evaluated to represent that level of performance. The top rated SO₂ removal rate is 98% removal and can be achieved by replacing the existing wet FGD system with either a new wet FGD system or a ReACT system. As a wet FGD system is a well demonstrated technology for high sulfur fuel and ReACT has only been applied on low sulfur fuel this evaluation will focus on the new wet FGD option to evaluate the top rated option. As shown in Table 3-3, ReACT is not expected to have better performance than wet FGD in operating conditions encountered at MRYS.

3.4.1 Cost Evaluation

The following sections evaluate the top two ranked control options for Unit 2, replacing the existing wet FGD system with a new wet FGD system, and upgrading the Unit 2 scrubber. A new wet FGD was not considered for Unit 1, as the existing wet FGD began operations in 2011 as part of the previous BART/BACT analysis and is within the previously evaluated useful life. The top ranked control option for Unit 1, modify the existing wet FGD, is evaluated.

3.4.1.1 New Wet FGD Capital Cost Estimate

Cost estimates for the new wet FGD SO₂ control technologies were completed utilizing the 'IPM Model – Updates to Cost and Performance for APC Technologies Wet FGD Cost Development Methodology' available from the U.S. Environmental Protection Agency and supplemented with engineering estimates based upon Burns & McDonnell's in-house experience. The IPM Model Update is a formula-based report that was specifically developed to estimate the cost of wet FGD technologies for utility power plants. The report was prepared for the EPA in January 2017. The report is available for download from the U.S. EPA website at www.epa.gov/airmarkets/documentation-epas-power-sector-modeling-platform-v6.

As a conservative (lowest cost) approach, this evaluation only considered the 'Absorber Island' portion of the new scrubber cost at a retrofit factor of 1.0 and supplemented this with engineering estimates for new duct work, connecting piping and space modifications required to fit the absorber. This approach assumes all of the existing balance of plant (BOP) systems are capable of supporting the new system with

no upgrades. Further, it is assumed there is no change in operating staff and only a proportional change in the variable operating cost. These conservative assumptions minimize the overall project cost resulting in a conservatively low dollars per ton control cost.

For the addition of a new wet FGD absorber, Unit 2 will require new ductwork to connect to the new wet FGD system, modifications to the coal pile to create space for the new system and electrical replacement/upgrades for the new scrubber or a significantly extended outage to allow for the existing wet FGD system to be shut down while the new system is tied in, commissioned and started up. The SO₂ control system cost is representative of a typical furnish and erect contract by a wet FGD system supplier. Economic information utilized as input into the model is given in Table 1-1. The results of the capital cost estimates are given in Table 3-4.

Table 3-4: Capital Cost Estimate for MRYS Unit 2 Wet Lime FGD System

DIRECT COSTS	Unit 2 Estimated Cost (\$)
New FGD Absorber	
FGD Island	\$51,586,000
BOP Costs	
Mechanical Contract	\$54,000,000
Foundations and Steel	\$4,461,000
BOP Total Direct Cost =	\$58,461,000
Total Direct Cost =	\$110,047,000
INDIRECT COSTS	
Engineering 10% of DC	\$11,005,000
Escalation to 2021	\$10,204,000
Indirect Cost Subtotal	\$21,209,000
Contingency (20% of DC)	\$13,126,000
Prime Contractor's Fee (3% of DC)	\$10,107,000
Total Capital Requirement	\$154,489,000

The total estimated capital cost estimate for a complete new wet FGD absorber is \$154,489,000 or \$324kW.

3.4.1.2 Wet FGD Modification Capital Cost Estimate

Cost estimates for retrofitting the existing wet FGD systems were based on the equipment modification and associated pricing provided by the OEM and supplemented with engineering estimates for installation based upon Burns & McDonnell's in-house experience.

This evaluation assumes all of the existing balance of plant (BOP) systems are capable of supporting the new system with no further upgrades. Further, it is assumed there is no change in operating staff and only a proportional change in the variable operating cost. These conservative assumptions minimize the overall project cost resulting in a conservatively low dollars per ton control cost.

The capital cost estimate for the Unit 1 wet FGD system modification includes the OEM recommendation to replace three out of the four recirculation pump motors to increase the liquid to gas ratio in the scrubber. During this investigation the existing electrical system and foundation associated with the pump was reviewed and is believed to be sufficient to support this upgrade with no further modifications.

The capital cost estimate for the Unit 2 wet FGD system modification includes the OEM recommendation to replace all of the absorber spray nozzles with dual flow nozzles. The OEM did not recommend upgrading the pumps on Unit 2 due to velocity limitations in the riser pipe and headers and did not recommend upgrading the riser headers and spray headers to accommodate more flow as these upgrades could compromise or complicate the conditions of the existing towers. The results of the capital cost estimates for the FGD system modifications are given in Table 3-5.

Table 3-5: Capital Cost Estimate for MRYS Unit 1 Wet FGD System Modification

DIRECT COSTS	Unit 1 Estimated Cost (\$)	Unit 2 Estimated Cost (\$)
Modified FGD System		
FGD Modification Equipment Cost	\$569,000	\$1,011,000
BOP Costs		
Mechanical Contract	\$0	\$280,000
Electrical and Controls	\$16,000	\$0
BOP Total Direct Cost =	\$16,000	\$280,000
Total Direct Cost =	\$585,000	\$1,291,000
INDIRECT COSTS		
Engineering 10% of DC	\$58,000	\$129,000
Escalation to 2021	\$54,000	\$120,000
Indirect Cost Subtotal	\$112,000	\$249,000
Contingency (20% of DC)	\$70,000	\$154,000
Prime Contractor's Fee (3% of DC)	\$54,000	\$119,000
Total Capital Requirement	\$821,000	\$1,813,000

The total estimated capital cost for upgrades to the Unit 1 wet FGD system is \$821,000, or \$3.2/kW.

The total estimated capital cost for upgrades to the Unit 2 wet FGD system is \$1,813,000, or \$3.8/kW.

3.4.1.3 New Wet FGD O&M Cost Estimate

The annual operating and maintenance costs (O&M) costs are comprised of fixed costs (maintenance and labor) and variable cost (consumables). The operating and maintenance costs are evaluated as additional costs beyond the existing wet FGD system as the current costs are part of the baseline operating conditions. The operating labor cost of a new system is not expected to be significantly different than the existing system over the life of the equipment. No additional operating labor has been assumed.

Variable costs include reagent, makeup water, FGD byproduct disposal and auxiliary power costs. The estimated annual costs for these consumables are based on the incremental consumption rates change between the existing removal rate and the new removal rate and the unit cost information provided in Table 1-1 Economic Design Criteria.

Table 3-6: O&M Cost Estimate for a New MRYS Unit 2 Wet Lime FGD System

Fixed Costs	
Operating Labor	\$0
Admin and Support labor	\$0
Maintenance Material and Labor	\$3,301,000
Total Fixed O&M Costs =	\$3,301,000
Variable Costs	
Lime Reagent	\$29,000
Byproduct Disposal	\$323,000
Auxiliary Power	\$854,000
Total Variable O&M Costs =	\$1,206,000
Total Annual O&M Costs	\$4,507,000
Net Annual O&M Cost (\$/MWh)	1.27

3.4.1.4 Wet FGD Modification O&M Cost Estimate

The annual operating and maintenance costs (O&M) costs are comprised of fixed costs (maintenance and labor) and variable cost (consumables). The operating and maintenance costs are evaluated as additional costs beyond the existing wet FGD system as the current costs are part of the baseline operating conditions. The operating labor cost of a new system is not expected to be significantly different than the existing system over the life of the equipment. No additional operating labor has been assumed.

Variable costs include reagent, makeup water, FGD byproduct disposal and auxiliary power costs. The estimated annual costs for these consumables are based on the incremental consumption rates change between the existing removal rate and the new removal rate and the unit cost information provided in Table 1-1 Economic Design Criteria.

Table 3-7: O&M Cost Estimate for MRYS Unit 1 and 2 Wet Lime FGD System Modification

Fixed Costs	Unit 1	Unit 2
Operating Labor	\$0	\$0
Admin and Support labor	\$0	\$0
Maintenance Material and Labor	\$18,000	\$39,000
Total Fixed O&M Costs =	\$18,000	\$39,000
Variable Costs		
Lime Reagent	\$86,000	\$162,000
Byproduct Disposal	\$8,000	\$15,000
Auxiliary Power	\$228,000	\$376,000
Total Variable O&M Costs =	\$322,000	\$553,000
Total Annual O&M Costs	\$340,000	\$592,000
Net Annual O&M Cost (\$/MWh)	0.18	0.17

O&M Cost represent costs above the baseline (existing system)

3.4.1.5 Levelized Total Annual Cost

In order to effectively compare the cost of installing, operating, and maintaining the SO₂ control systems, capital and O&M costs should be evaluated on a levelized basis.

The Levelized Total Annual Cost (LTAC) for SO₂ control systems was calculated based on overnight construction period (2021), followed by a 20 year service life ending December 31, 2041. O&M costs were based on first year (2021) cost. No salvage value was assumed at the end of the service life for any of the alternatives. The results are presented in Table 3-8 and Table 3-9 along with the emissions reduction, resultant emissions rate and the Unit Control Cost. The Unit Control Cost is the LTAC divided by the annual tons of additional SO₂ emissions that would be controlled by implementation of the respective alternative.

Table 3-8: MRYS Unit 1 SO₂ Control System Levelized Total Annual Cost

SO₂ Control Alternative	Emission Rate lb/10⁶ Btu	Annual Emission (tpy)¹	Annual Emission Reduction (tpy)¹	Installed Capital Cost (\$2021)²	Annual O&M Cost (\$2021)	Levelized Total Annual Cost (\$2021)³	Actual Unit Control Cost (\$/ton)⁴
Modified Wet FGD ⁵	0.10	934	374	821,000	340,000	408,701	1,093
Baseline	0.14	1,308	Baseline				

1. Based on baseline heat input of 2,510 MMBtu/hr at 85% capacity factor

2. All Costs in 2021 dollars.

3. For LTAC calculation, Capital Recovery Factor = 0.08368 and first year O&M Cost.

4. Overall control cost is LTAC divided by actual annual emissions reduction of each alternative.

5. Emission rate based on future higher sulfur coal (96% removal).

Table 3-9: MRYS Unit 2 SO₂ Control System Levelized Total Annual Cost

SO ₂ Control Alternative	Emission Rate lb/10 ⁶ Btu	Annual Emission (tpy) ¹	Annual Emission Reduction (tpy) ¹	Installed Capital Cost (\$2021) ²	Annual O&M Cost (\$2021) ²	Levelized Total Annual Cost (\$2021) ³	Actual Unit Control Cost (\$/ton) ⁴	Incremental Unit Control Cost (\$/ton)
New Wet FGD	0.065	1,136	1,486	154,489,000	6,133,196	19,060,732	12,826	29,934
Modified Wet FGD ⁵	0.10	1,748	874	1,813,000	592,000	743,684	851	
Baseline	0.15	2,622	Baseline					

1. Based on baseline heat input of 4,696 MMBtu/hr at 85% capacity factor

2. All Costs in 2021 dollars.

3. For LTAC calculation, Capital Recovery Factor = 0.08368 and first year O&M Cost.

4. Overall control cost is LTAC divided by actual annual emissions reduction of each alternative.

5. Emission rate based on future higher sulfur coal (96% removal).

The annual tons of SO₂ reduction in this RHCT analysis are calculated as the difference between the baseline emission rate and the controlled emissions assumed to be at the same heat input and unit operating time.

3.4.1.6 Cost Estimate Conclusion

In the RHCT guidelines, EPA does not provide definition, or even discussion of what Unit Control Costs are considered reasonable or unreasonable. NDDH has indicated that costs below \$5,000 per ton may be considered to be reasonable.

The Actual Unit Control Cost are used to evaluate the technology alternatives on a cost effectiveness basis. As can be seen from a review of Table 3-9, the cost of the new Unit 2 wet FGD alternative is excessively high with an actual and incremental control cost far greater than \$5,000 dollars per ton.

As can be seen from a review of Table 3-8 and Table 3-9, the wet FGD modification alternatives for both units are not high, with a Actual Unit Control Cost of \$851-\$1,093 per ton.

3.4.2 Energy Impacts

The energy impacts of replacing the existing U2 wet FGD with a new wet FGD, or of upgrades to the existing wet FGD in the case of Unit 1, in terms of both estimated kW of energy usage and the percent of total generation, are given in Table 3-10 and Table 3-11. The primary energy impacts of the wet FGD alternative consists of the additional electrical load resulting from pumps and reagent preparation.

Building HVAC and interior and exterior lighting loads are considered minimal.

Table 3-10: Energy Requirement of MRYS Unit 1 FGD Upgrades

RHCT Alternative	Energy Demand (kW)	Percent of Nominal Generation
Existing Wet FGD	5,170	2.2%
Upgraded Wet FGD	5,756	2.5%

Table 3-11: Energy Requirement of MRYS Unit 2 New FGD

RHCT Alternative	Energy Demand (kW)	Percent of Nominal Generation
Existing Wet FGD	9,658	2.2%
Upgraded Wet FGD	10,623	2.4%
New Wet FGD	11,853	2.7%

3.4.3 Non-Air Quality Environmental Impacts

Non-air quality environmental impacts of replacing the existing wet FGD with a new wet FGD or retrofitting the existing FGD systems are expected to be very similar to the impacts of the existing system. These may include hazardous waste generation, solid and aqueous waste streams. The primary change anticipated due to the use of a new wet FGD or modifying the existing FGD systems will be an incremental increase in the solids disposal rate as additional removal of SO₂ will result in increased byproduct.

While the economic evaluation of a new wet FGD system assumes overnight installation, the actual process to bid, design, purchase, and install a retrofitted new wet FGD system can take five years to implement. The actual process to bid, design, purchase, and install a retrofits to an existing wet FGD system can take two to three years to implement.

3.4.4 SO₂ Control Technology Evaluation Conclusion

The energy impacts of a new wet FGD system are only incrementally higher than the existing system and are primarily driven by the increase in SO₂ removal. These incremental increases are acceptable.

The time period to install a new wet FGD system is significantly longer than the second ranked option (retrofitting the existing wet FGD) and would result in years of higher emission rates to achieve only a marginal increased removal rate. This would result in years of higher emissions before the RHCT would be installed.

Considering the existing systems are being replaced with like systems, there could be years of implementation delay with a new system for marginal removal improvement, and the high dollars per ton control cost includes low capital cost assumptions this evaluation rejects the top ranked control technology for Unit 2 (new wet FGD) as RHCT.

While this is not used as the reason for the rejection of this top ranked option, comparison to the second ranked option [an upgrade to the existing wet FGD] shows that the high levelized cost differential and low differential removal rate of the new FGD option result in an excessive incremental dollars per ton removed of almost \$30,000 per ton.

The time period to modify the existing wet FGD systems is significantly shorter than installing other new systems and would result in lower emission rates sooner than other options. The average control cost to modify the existing wet FGD systems is well below \$5,000 per ton. This evaluation results in modification of the wet FGD systems as RHCT.

4.0 REGIONAL HAZE CONTROL TECHNOLOGY RESULTS

This report presents the analysis of control technologies for nitrogen oxides (NO_x), and sulfur dioxide (SO₂) for Minnkota Power Cooperative Inc.'s (Minnkota's) Milton R. Young Station (MRYS) Units 1 and 2. The final result of this analysis is a Regional Haze Control Technology (RHCT) emission rate for each unit based upon "the costs of compliance, the energy and non-air quality environmental impacts of compliance, any pollution control equipment in use at the source, the remaining useful life of the source..." (70 FR 39163). The presented emission rates in this section are the RHCT results.

The first four steps of RHCT are usually used to identify technologies, determine feasibility and evaluate cost, energy, non-air quality and useful life impacts. This analysis reviewed technologies on these factors starting from the baseline of the existing units that include ASOFA/SNCR and wet scrubbers. The RHCT analysis does not review technologies that do not achieve at least the baseline level of performance.

As stated in previous sections of the report, the first four steps of the technology evaluation provided for in the Guidelines were completed for both Units. Each pollutant required a different approach in order to determine RHCT emission rate. This section provides a brief description of the approach used for each pollutant and summarizes the results.

For NO_x emissions, the top ranked technically feasible control technology for both units is the use of Rich Reagent Injection (RRI) in combination with Selective Non-Catalytic Reduction (SNCR) and Advanced Separated Overfire Air (ASOFA). However, the RRI+SNCR system is not an economically effective NO_x control alternative for either Unit 1 or Unit 2 with average control cost of \$6,829 – \$13,769.

The Unit Control Costs for the next top ranked control technology, Optimized SNCR system, is above \$5,000 per ton on Unit 1 (\$45,603 per ton) and Unit 2 (\$5,886). From an economic analysis viewpoint, optimized SNCR systems are not economically effective NO_x control alternative for either unit.

This evaluation results show the existing SNCR system as the top ranked alternative.

For SO₂ emissions, the top ranked technology for Unit 2 was to replace the existing wet scrubber with a new wet scrubber. This technology was evaluated and rejected primarily because it was determined to be excessively costly on an actual dollars per ton removed basis (\$12,826 per ton). Furthermore this top

ranked control technology provided only limited additional removal for an order of magnitude additional costs compared to the second ranked control technology.

The next highest ranked control technology (and also top ranked for Unit 1) is to retrofit the existing wet scrubbers to increase removal. The OEM of the Unit 1 scrubber was engaged to evaluate how to increase the Unit 1 scrubber removal and re-evaluate a previous study they performed to increase removal in the Unit 2 scrubber. The mechanical upgrades the OEM included are replacing pump motors and changing nozzle designs. The various changes to operating conditions were evaluated based on the plant's previous operating history and experience to consider which conditions will improve removal, working with the existing system and not impact reliability. There are no sufficient economic or energy reasons to reject modifying the existing scrubbers. There are non-environmental reasons taking are into consideration associated with scrubber operational changes due to long term impact to the scrubber ponds. Based upon this analysis modifying the existing scrubbers is a RHCT option for SO₂ emissions.

Table 4-1 and Table 4-2 summarize the control technologies and associated emission rates for each pollutant and for each unit. The RHCT emission rates are presented as a 30-day rolling average to account for variations in boiler operation, and fuel sulfur content.

Table 4-1: RHCT 30-Day Rolling Average Emission Rate, MRYS Unit 1

Pollutant	Control Technology	Emission Rate (lb/million Btu)
NO _x	Existing Selective Non-Catalytic Reduction (SNCR) and Advanced Separated Over Fire Air (ASOFA) ¹	0.36
SO ₂	Modify the existing Wet Flue Gas Desulfurization (FGD) system ²	0.10

1: Excludes startups. See referenced BACT analysis for a detailed discussion.

Table 4-2: RHCT 30-Day Rolling Average Emission Rate, MRYS Unit 2

Pollutant	Control Technology	Emission Rate (lb/million Btu)
NO _x	Existing Selective Non-Catalytic Reduction (SNCR) and Advanced Separated Over Fire Air (ASOFA) ¹	0.35
SO ₂	Modify the existing Wet Flue Gas Desulfurization (FGD) system ²	0.10

1: Excludes startups. See referenced BACT analysis for a detailed discussion.

The four factor analysis was completed based on a request by the North Dakota Department of Health (NDDH) while utilizing the EPA 2016 Guidance document. The NDDH has requested this information for the purpose of WRAP modeling. As EPA has indicated the Regional Haze Roadmap may be updated, and the results of the WRAP modeling will provide new information to be considered, Minnkota reserves

the right to modify the 4 Factor analysis once the Regional Haze Roadmap, any additional guidance and the results of the WRAP modeling are available. In addition, Minnkota reserves the right to conduct a 5th Factor based on visibility modeling once the results of the WRAP modeling are available. This analysis is provided to assist the NDDH in the WRAP modeling and is not intended to serve as an agreement by Minnkota to any changes in permitted emission limits or permit conditions.

May 29, 2019

Mr. Jim Semerad
Director, Division of Air Quality
North Dakota Department of Environmental Quality
Gold Seal Center, 918 East Divide Ave
Bismarck, ND 58501-1947

Dear Mr. Semerad:

Re: Four-Factor Analysis – Milton R. Young Station Unit 1 and Unit 2

Minnkota appreciates the North Dakota Department of Environmental Quality's (NDDEQ) review of the Milton R. Young Station (MRYS) four-factor analysis submitted for the second implementation period of the Regional Haze Rule. As a part of NDDEQ's review, six comments were provided to Minnkota (dated March 18, 2019) as the basis for revising our first report, which was submitted on January 31, 2019. The following provides Minnkota's responses to each of these six comments. Additionally, two hardcopies of Minnkota's revised four-factor analysis report are enclosed.

- 1) Summary of NDDEQ Comment: *"All estimates of costs should be based on current (2019) dollars not 2021 dollars...All estimates of capital costs must be consistent with [EPA's] Control Cost Manual."*

Minnkota Response: The revised report reflects 2019 dollars and all capital costs are now consistent with the Control Cost Manual. (Updates appear throughout report impacting cost values.)

- 2) Summary of NDDEQ Comment: *"...baseline emission rates were based on the maximum 30-day rolling average from 2014-2018. Baseline emissions should represent expected future annual emissions..."*

Minnkota Response: Per our discussion with NDDEQ, baseline emissions for both Unit 1 and Unit 2 have been revised and are now based on a 3-year annual average from 2016-2018. For each unit, this baseline period represents two non-major outage years and one major outage year. Emissions data submitted as required by 40 CFR Part 75 were used to determine the baseline emissions. (Discussed in section 1.1.5.)

- 3) Summary of NDDEQ Comment: *“The costs of Rich Reagent Injection (RRI) appears to be excessive...Please revise the estimates for both units or provide a detailed explanation for the high cost.”*

Minnkota Response: The cost estimates for RRI used in the first draft report were determined using: (1) computational fluid dynamics modeling, boiler mapping and RRI system design in conjunction with advanced separated overfire air (ASOFA) and selective non-catalytic reduction (SNCR) by technology vendor Fuel Tech, and (2) installation and balance of plant (BOP) costs determined by Burns & McDonnell (BMcD) with input from Minnkota. The enclosed revised report, as well as the separately submitted (through confidentiality) Fuel Tech vendor proposals, provide complete details. Minnkota firmly believes that the costs used in the first report are accurate and represent actual costs for installation of RRI with ASOFA and SNCR at MRYS. As such, these costs have not been changed in the revised report. (Discussed in Sections 2.5.1.1, 2.5.1.2 and the addition of Appendices A & B.)

- 4) Summary of NDDEQ Comment: *“Many cost estimates throughout the analysis are based on vendor budgetary quotes or engineering estimates. When cost estimates are not based on EPA’s Control Cost Manual, evidence for the estimate must be provided...”*

Minnkota Response: As requested, the revised report contains discussion and evidence of vendor budgetary quotes and engineering estimates where used. BMcD has prepared a more detailed breakdown of installation and BOP costs based on a combination of vendor quotations and engineering estimates; this is included as appendices to the revised report. Additionally, confidential vendor proposals from Fuel Tech (NO_x control systems) and Marsulex Environmental Technologies (SO₂ control systems) have been submitted separately via confidential avenues. Minnkota is confident that the costs used accurately represent the actual costs for installing the emissions control systems at MRYS. (Discussed in Sections 2.5.1.1, 2.5.1.2, 3.5.1.2 and the addition of Appendices A & B.)

- 5) Summary of NDDEQ Comment: *“...“levelizing” of costs using the normal electric utility industry method is not acceptable...The costs must be revised to be consistent with the Control Cost Manual.”*

Minnkota Response: The actual cost estimating methods used in the first report were consistent with the Control Cost Manual. However, the nomenclature was not consistent. Therefore, in the revised report, the nomenclature has been updated to be consistent with the Control Cost Manual. The “annualized total cost” (ATC) represents the annual cost of procurement, construction and operation over a 20-year design life, in current day dollars. The ATC represents an annual payment in current day dollars sufficient to finance the project over its entire life. The ATC is the sum of the annualized capital cost and the first year operating & maintenance cost. (Revised Section 1.1.6.)

- 6) Summary of NDDEQ Comment: “...the projected emissions (tpy) for a “Modified Wet FGD” were based on future higher sulfur coal. It appears the baseline emission rates were also based on future higher sulfur coal. ...the high baseline emission rates should be explained.”

Minnkota Response: The projected emissions have been modified to reflect a common wet FGD inlet condition. The common/baseline wet FGD inlet condition is the average continuous emissions monitor readings for the 2016-2018 baseline years. (Discussed in section 1.1.5.)

In addition to Minnkota’s above responses to the NDDEQ comments and our enclosed revised four-factor analysis report, a separate submission containing confidential documents has also been provided.

Thank you for the attention given to the MRYs four-factor analysis report. If you have any further questions regarding this revised report, please contact me by email at dlaudal@minnkota.com or by phone at (701) 795-4216.

Sincerely,

EXECUTIVE SUMMARY

This report presents the Regional Haze Control Technology (RHCT) analysis for nitrogen oxides (NO_x), and sulfur dioxide (SO₂) for Minnkota Power Cooperative, Inc.'s Unit 1 and Square Butte Electric Cooperative's Unit 2 at the Milton R. Young Station (MRYS)

The MRYS is a two-unit station, located near Center, North Dakota. Unit 1 (257 MWg) commenced commercial operation in 1970, and Unit 2 (477 MWg) commenced operation in 1977. Both units employ Babcock and Wilcox cyclone boilers, and both boilers fire North Dakota lignite supplied from BNI Coal, Ltd's Center Mine. Each unit is equipped with Advanced Separated Over Fire Air (ASOFA) and selective non-catalytic reduction (SNCR) for NO_x control. Each unit is equipped with wet flue gas desulfurization (FGD) for SO₂ control. Each unit employs an electrostatic precipitator (ESP) for particulate control. Each unit employs halide injection and activated carbon injection for the control of mercury.

On July 6, 2005, the United States Environmental Protection Agency (U.S. EPA or EPA) finalized the Regional Haze Regulations (RHR) and Guidelines for BART Determinations. In July of 2016, the EPA issued draft guidance for the second implementation period of the RHR. The guidance document requires a "four factor analysis" to be conducted for sources that have the potential to impair visibility in Class 1 areas. The four statutory factors are:

- The cost of compliance
- The time necessary for compliance
- The energy and non-air quality environmental impacts of compliance
- The remaining useful life of the source

This report presents the required "four factor analysis" for MRYS. Note that for MRYS, Minnkota has determined that the "remaining useful life of the source" is not a relevant factor in the analysis. The term "RHCT analysis" is used throughout this report to refer to the analysis that has been conducted in compliance with the requirements of EPA's July 2016 draft guidance.

The guidance document, in general, indicates that the goal of the second implementation period is to evaluate all sources for incremental visibility improvement, including those sources that were previously determined to be Best Available Retrofit Technologies (BART)-eligible. MRYS Unit 1 and Unit 2 were previously determined to be BART-eligible by the North Dakota Department of Environmental Quality (NDDEQ).

This RHCT evaluation is intended to inform NDDEQ of the future potential to reduce emissions at MRYS and the cost associated with these reductions. This evaluation is based on a top down evaluation of control technologies and will provide NDDEQ an emission rate for visibility impairment modeling.

There are five predefined steps for conducting a RHCT analysis. Steps 1 through 3 include identifying control technologies, evaluating feasibility, and ranking feasible options by control effectiveness. Step 4 involves a technical evaluation of economic, energy, and non-air environmental impacts related to each feasible control technology. This evaluation addresses these first four steps, resulting in an emission rate for the Step 5 Class 1 area visibility impairment impact analysis.

Unlike the previous BART analysis, this analysis reviews technologies on a ‘Top Down’ basis. The best (lowest emitting) feasible technology that is acceptable (considering economic, energy and non-air impacts) will be evaluated by NDDEQ for visibility impact reduction. The results of conducting the four step analysis will provide a recommendation to NDDEQ of a potential RHCT and the associated emission rate.

This analysis used several reference works, including the RACT/BACT/LAER Clearinghouse (RBLC), to identify which control technologies to evaluate. The technologies were reviewed for feasibility and those deemed infeasible were eliminated from further study. The feasible control technologies were then ranked by control efficiency with estimates of costs necessary to implement, operate, and maintain such technologies. The top ranked technology was evaluated based upon the average cost (dollars per ton removed) to determine if it was acceptable. The final RHCT results are summarized in the tables below. The RHCT emission rates are presented as annual average emission rates to account for variations in boiler operation, and fuel quality (including sulfur content). These are the emission rates utilized in the economic evaluation.

MRYS Unit 1 RHCT Annual Average Emission Rates

Pollutant	Control Technology	Emission Rate (lb/million Btu)
NO _x	Existing Selective Non-Catalytic Reduction and Advanced Separated Over Fire Air	0.332
SO ₂	Modify the existing Wet Flue Gas Desulfurization system	0.061

MRYS Unit 2 RHCT Annual Average Emission Rates

Pollutant	Control Technology	Emission Rate (lb/million Btu)
NO _x	Existing Selective Non-Catalytic Reduction and Advanced Separated Over Fire Air	0.334
SO ₂	Modify the existing Wet Flue Gas Desulfurization system	0.057

The four factor analysis was completed based on a request by NDDEQ while utilizing the EPA 2016 Guidance document. The NDDEQ has requested this information for the purpose of Western Regional Air Partnership (WRAP) modeling, and potentially for emissions reductions for the second implementation period. The emission rates in this report are for WRAP modeling and are not proposed permit emission limits. As EPA has indicated, the Regional Haze Roadmap may be updated, and the results of the WRAP modeling will provide new information to be considered. Minnkota reserves the right to modify the four factor analysis once the Regional Haze Roadmap, any additional guidance and the results of the WRAP modeling are available. In addition, Minnkota reserves the right to conduct a 5th factor analysis based on visibility modeling once the results of the WRAP modeling are available.

This analysis is provided to assist the NDDEQ in the WRAP modeling and is not intended to serve as an agreement by Minnkota to any changes in permitted emission limits or permit conditions.

1.0 INTRODUCTION

This report presents the Regional Haze Control Technology (RHCT) analysis for nitrogen oxides (NO_x), and sulfur dioxide (SO₂) for Minnkota Power Cooperative, Inc.'s Unit 1 and Square Butte Electric Cooperative's Unit 2 at the Milton R. Young Station (MRYS)

The MRYS is a two-unit station, located near Center, North Dakota. Unit 1 (257 MWg) commenced commercial operation in 1970, and Unit 2 (477 MWg) commenced operation in 1977. Both units employ Babcock and Wilcox cyclone boilers, and both boilers fire North Dakota lignite supplied from BNI Coal, Ltd's Center Mine. Each unit is equipped with Advanced Separated Over Fire Air (ASOFA) and selective non-catalytic reduction (SNCR) for NO_x control. Each unit is equipped with wet flue gas desulfurization (FGD) for SO₂ control. Each unit employs an electrostatic precipitator (ESP) for particulate control. Each unit employs halide injection and activated carbon injection for the control of mercury.

The United States Environmental Protection Agency (U.S. EPA or EPA) finalized the Regional Haze Regulations (RHR) and Guidelines for Best Available Retrofit Technology (BART) Determinations¹ in the Federal Register on July 6, 2005 (70 FR 39104). In July 2016, the EPA issued draft guidance for the second implementation period of the RHR². The draft guidance for the second implementation period retains many aspects of the BART guidelines.

The guidance documents, in general, indicate the goal of the second implementation period is to evaluate all sources for incremental visibility improvement including those sources that were previously BART-eligible. Both units at MRYS were previously determined to be BART-eligible by the North Dakota Department of Environmental Quality (NDDEQ). BART is defined as "an emission limitation based on the degree of reduction achievable through the application of the best system of continuous emission reduction for each pollutant which is emitted by a BART-eligible source. The emission limitation must be established on a case-by-case basis, taking into consideration the technology available, the costs of compliance, the energy and non-air quality environmental impacts of compliance, any pollution control equipment in use at the source, the remaining useful life of the source, and the degree of improvement in

¹ "Regional Haze Regulations and Guidelines for Best Available Retrofit Technology (BART) Determinations"; Environmental Protection Agency; Federal Register, Volume 70, No. 128; July 6, 2005.

² "Draft Guidance on Progress Tracking Metrics, Long-Term Strategies, Reasonable Progress Goals and Other Requirements for Regional Haze State Implementation Plans for the Second Implementation Period", Environmental Protection Agency; Federal Register, Volume 81, No. 131; July 8, 2016.

visibility which may reasonably be anticipated to result from the use of such technology” (70 FR 39163). Note that for MRYS, Minnkota has determined that the “remaining useful life of the source” is not a relevant factor in the analysis.

The second implementation period guidance indicates a similar review to BART should be performed but in the second round the technology evaluation should be based on a ‘top down’ approach. The evaluation criteria are the same as the previous BART analysis, which is on a case-by-case basis considering availability, cost, energy and non-air quality impacts. However, in a ‘top down’ analysis the highest ranked technology that meets the acceptable criteria in the first four steps is the selected technology. The final determination of what top ranked technologies across the utility fleet will be accepted, if any, as the Regional Haze Control Technology (RHCT) is dependent on Step 5 (visibility modeling) and will be based on the modeling performed by the Western Regional Air Partnership (WRAP). This RHCT evaluation will be used by the NDDEQ as a tool to evaluate the potential to reduce emissions at MRYS and the cost associated with these reductions.

1.1 RHCT Analysis Process

The general steps for determining RHCT for each pollutant are virtually the same as the previous BART steps (70 FR 39164) and are as follows:

STEP 1 - Identify all available retrofit control technologies.

STEP 2 - Eliminate technically infeasible options.

STEP 3 - Evaluate control effectiveness of remaining control technologies.

STEP 4 - Evaluate the following impacts for each feasible control technology and document results:

The cost of compliance.

The time required for compliance.

The energy and non-air quality environmental impacts of compliance.

The remaining useful life of the source.

STEP 5 – Evaluate the visibility impacts.

Unlike the previous BART analysis where all five steps were performed at once, the 2016 EPA Draft Guidance’s approach for the second implementation period of the regional haze program is breaking the first four steps apart from the fifth step. The first four steps are performed on a ‘top down’ basis to determine the top ranked control technology that is applicable to each source. The fifth step, evaluation of visibility impacts, is being conducted by WRAP. The WRAP evaluation of visibility impacts will then

be used by the State (as part of the development of the State Implementation Plan) to determine which sources, if any, are needed to fulfill the Reasonable Progress Goals required by the RHR.

Minnkota retained Burns & McDonnell to assist in the completion of the first four steps of the RHCT analysis for MRYS. Burns & McDonnell is a full service engineering, architectural, construction and environmental firm. The company plans, designs and constructs electric generating facilities and has been providing environmental services to the power industry since the 1970s. As a result of their long history providing these services, Burns & McDonnell has extensive experience in permitting, Best Available Control Technology (BACT) studies, BART studies and control technology analysis similar to a RHCT analysis.

1.1.1 Identification of Available Retrofit Control Technologies

The initial step in the RHCT determination is the identification of available retrofit control technologies. In order to identify the available control technologies, several reference works are consulted. A preliminary list of control technologies and their estimated capabilities is then developed.

1.1.2 Elimination of Technically Infeasible Options

The second step of the RHCT process is to evaluate the control processes that have been identified and determine if any of the processes are technically infeasible. The BART guidelines are applicable to this RHCT analysis. These guidelines discuss consideration of two key concepts during this step in the analysis. The two concepts to consider are the “availability” and “applicability” of each control technology.

A control technology is considered available “if the source owner may obtain it through commercial channels, or it is otherwise available in the common sense meaning of the term,” or “if it has reached the stage of licensing and commercial availability.” On the contrary, a control technology is not considered available, “in the pilot scale testing stages of development.” (70 FR 39165) When considering a source’s applicability, technical judgment must be exercised to determine “if it can reasonably be installed and operated on the source type.” The EPA also does not “expect a source owner to conduct extended trials to learn how to apply a technology on a totally new and dissimilar source type.” (70 FR 39165) “A technology that is available and applicable is technically feasible.” (70 FR 39165)

A control technology is considered technically infeasible if physical, chemical or engineering principles conclude that technical difficulties would preclude use of the control option on the emission unit under review.

1.1.3 Evaluate Technically Feasible Control Option by Effectiveness

The third step in the RHCT analysis is to evaluate the control effectiveness of the technically feasible alternatives. During the feasibility determination in step 2 of the analysis, the control efficiency is reviewed and presented with the description of each technology. The evaluation of the technically feasible alternatives concludes with the alternatives ranked in descending order of control effectiveness.

1.1.4 Four Factor Impact Analysis

Step four in the analysis procedure is the impact analysis. The BART Determination Guidelines (70 FR 39166) and the draft guidelines for the second implementation period (81 FR 44608) each list four factors to be considered in the impact analysis. The RHCT evaluation will consider the following four factors in the impact analysis:

- The costs of compliance
- The time required for compliance
- The energy and non-air quality environmental impacts of compliance
- The remaining useful life of the source.

The first three of the four factors considered in the impact analysis are discussed in the associated pollutant section. The remaining useful life of the source would have been included as part of the cost of compliance, however for MRYS, Minnkota has determined that the “remaining useful life of the source” is not a relevant factor in the analysis.

In the second implementation period, the impact analysis is performed on a ‘top down’ basis. The highest ranked (lowest emitting) technology is evaluated on the above factors for acceptability. If the top-ranked control technology is unacceptable, then the next highest ranked control technology is evaluated. This process continues until the highest ranked acceptable technology is identified.

1.1.5 Baseline Emissions

The cost of compliance evaluation is typically performed on an annualized dollars per ton of pollutant removed basis. In order to determine the tons removed by a proposed technology, a baseline emission rate must be determined as a basis for the comparison. The MRYS units both have existing SO₂ and NO_x pollution control systems in service, and the baseline is calculated with those systems in operation. Since the control costs are based on annual costs, the baseline emission rates need to be based on a similar long-term basis.

The baseline emission rates were developed by evaluating the three most recent years (2016-2018) for Unit 1 and for Unit 2. This baseline was established in consultation with the NDDEQ. The baseline period, for each unit, contains two non-major outage years and one major outage year. Previously submitted emissions data as required by 40 CFR Part 75 were used to determine the baseline emissions. A summary of the baseline emission rates and annual tons of emissions is provided in Table 1-1 and Table 1-2 for Unit 1 and Unit 2, respectively.

The scrubber inlet SO₂ conditions for each unit at MRYS are measured using continuous emissions monitors (CEMS). These inlet conditions during the baseline period for Unit 1 (2.327 lb/MMBtu) and Unit 2 (2.487 lb/MMBtu) will be used as the basis for future sulfur content at the inlet of each scrubber.

Table 1-1: MRYS Unit 1 Baseline Emissions (2016-2018)

Pollutant	Control Technology	Emissions, lb/MMBtu	Emissions, tpy	Heat Input, MMBtu/year
SO ₂	Wet FGD	0.0739	777	20,726,417
NO _x	ASOFA/SNCR	0.332	3,435	20,726,417

Table 1-2: MRYS Unit 2 Baseline Emissions (2016-2018)

Pollutant	Control Technology	Emissions, lb/MMBtu	Emissions, tpy	Heat Input, MMBtu/year
SO ₂	Wet FGD	0.126	2165	34,354,956
NO _x	ASOFA/SNCR	0.334	5,735	34,354,956

1.1.6 Methodology for Estimated Costs

The cost summary of each control technology alternative is presented in the section for each pollutant. Installed capital and annual operating and maintenance (O&M) cost estimates for each alternative are presented individually. The Annualized Total Cost (ATC) represents the annual cost of procurement, construction and operation over a 20-year design life, in current day dollars. The ATC is the sum of the annualized capital cost and the first year O&M cost and represents an annual payment in current day dollars sufficient to finance the project over its entire life.

In determining the ATC, a Capital Recovery Cost (CRC) is calculated to annualize the ‘overnight’ capital cost. The CRC is determined by multiplying the Net Present Value (NPV) by a Capital Recovery Factor (CRF). The CRF was calculated from the project economic conditions and then applied separately to the estimated capital costs. The equations used are shown below.

$$CRF = \left(\frac{i(1+i)^n}{(1+i)^n - 1} \right)$$

$$CRC = CRF \times NPV$$

Where,

CRF = Capital Recovery Factor

CRC = Capital Recovery Cost

NPV = Net Present Value of the capital investments required (overnight cost).

i = discount rate

n = design life in years

For the economic conditions described in Table 1-3, the CRF was calculated to be 0.08368.

Table 1-3: Economic Factors

Factor	Value
Total Possible Operating Hours per Year	8,760
Unit 1 Plant Capacity Factor, 2016-2018 baseline average	79.9%
Unit 2 Plant Capacity Factor, 2016-2018 baseline average	78.7%
Amortization Life, Years	20
Allowance for Funds Used During Construction	Not Included
Property Taxes, Insurance, %	Not Included
Amortization Rate for APC Capital Costs	Not Included
Interest Rate used in Capital Recovery Cost calculation	5.5%
Construction Cost Escalation	Not Included
Maintenance Material and Labor Cost, % of Direct Capital	3%
Non-Fuel O&M Escalation	Not Included
Fuel (coal and natural gas) Escalation	Not Included
Lost Electrical Generation Cost, \$/MW-hr	\$22.00
Auxiliary Electric Power Cost, \$/MW-hr	\$48.07
Reverse Osmosis Water, \$/kgal	\$9.03
Condensate water, \$/kgal	\$9.85
Urea 70% Solution, \$/ton	\$419.00
Lime, \$/ton	\$192.00
FGD Byproduct Disposal, \$/ton	\$6.00

(1) All costs are in 2019 dollars unless noted otherwise.

The capital cost (NPV in the equation above) is an ‘overnight’ installed cost for the equipment, in current day dollars, that does not include income tax effects, owners’ costs, escalation during construction, or interest costs from financing. The O&M cost used is the first-year costs, in 2019 dollars. The O&M cost

was not further inflated or otherwise annualized. The ATC is the sum of the annualized capital cost and the first year O&M cost. Therefore:

$$\text{ATC} = \text{CRC} + 1^{\text{st}} \text{ Year O\&M} = (\text{CRF} \times \text{NPV}) + 1^{\text{st}} \text{ Year O\&M} = 0.08368 \times \text{NPV} + 1^{\text{st}} \text{ Year O\&M}$$

The economic analyses presented in this report not only includes the estimated capital and annual O&M costs for each top ranked control technology, but also the ATC for economic comparison.

1.2 Background

MRYS is a steam electric generating plant with two units. Unit 1 employs ASOFA + SNCR for NO_x control, achieving 59% NO_x reduction. Particulate control is provided by a Research-Cottrell Electrostatic Precipitator (ESP) rated at approximately 99% control. Unit 1 has a Wet Flue Gas Desulfurization (FGD) system provided by Marsulex Environmental Technologies achieving compliance with a 30-day rolling average 95% SO₂ removal efficiency, based on inlet and outlet SO₂ CEMS, and exhausts to a 564-foot-tall chimney.

Unit 2 employs ASOFA + SNCR for NO_x control, achieving 60% NO_x reduction. Particulate control for Unit 2 is provided by a Wheelabrator-Lurgi ESP rated at approximately 99% control. Unit 2 has a Combustion Equipment Associates wet FGD system (modified by Combustion Engineering) achieving compliance with a 30-day rolling average 90% SO₂ removal efficiency, based on inlet and outlet SO₂ CEMS, and a 30-day rolling average 0.15 lb/MMBtu emission rate, and exhausts to a 550-foot-tall chimney.

Unit 1 began commercial operation on November 20, 1970 and Unit 2 on May 11, 1977.

2.0 NO_x RHCT EVALUATION

The RHCT analyses for NO_x emissions from MRYS Unit 1 and Unit 2 are described in this section. Technical descriptions of MRYS Unit 1 and Unit 2 boilers and existing air pollution control equipment are provided. Minnkota previously entered into a Consent Decree (CD) that required MRYS to install BACT for NO_x, which was determined to be SNCR systems with ASOFA on both units. These technologies are the current baseline condition for the two units.

2.1 NO_x Evaluation Basis

MRYS Unit 1 includes a B&W steam generator installed in 1970. The steam generator is a lignite-fired boiler with multiple cyclone-furnaces installed in parallel using balanced-draft and natural circulation. The boiler is fired by seven ten-foot diameter cyclone furnaces, arranged “three over four” across the front wall of the lower boiler. The unit has a tubular air heater installed between the boiler and the flue gas ductwork leading to the ESP. Unit 1’s boiler serves a turbine generator with a nameplate rating of 257 MWg³. The Unit 1 boiler at MRYS includes a unique coal conditioning system (drying, crushing, and feeding) for each cyclone furnace specifically designed to aid in proper combustion of the lignite fuel. Lignite fuel is the sole solid fuel for the plant and is supplied from the Center Mine, operated by BNI Coal, LTD, located adjacent to the site. The baseline emission rate of the Unit 1 boiler using the existing ASOFA/SNCR system is 0.332 lb NO_x/MMBtu, as described previously in Section 1.1.5.

MRYS Unit 2 is a B&W steam generator installed in 1977. The steam generator is a lignite-fired boiler with multiple cyclone-furnaces installed in parallel using balanced-draft and natural circulation assisted with circulation pumps. The boiler is fired by twelve ten-foot diameter cyclone furnaces, arranged “three over three” across the front and rear walls of the lower boiler. The unit has a tubular air heater installed between the boiler and the flue gas ductwork leading to the ESP. Unit 2’s boiler serves a turbine-generator with a nameplate rating of 477 MWg⁴. The Unit 2 boiler at MRYS includes a unique coal conditioning system (drying, crushing, and feeding) for each cyclone furnace specifically designed to aid in proper combustion of the lignite fuel. Lignite fuel is the sole solid fuel for the plant and is supplied from the Center Mine located adjacent to the site. The baseline emission rate of the Unit 2 boiler using the existing ASOFA/SNCR system is 0.334 lb NO_x/MMBtu, as described previously in Section 1.1.5.

2.2 Identification of Retrofit NO_x Control Technologies

The initial step in the RHCT determination is the identification of retrofit NO_x control technologies. In order to identify the applicable NO_x control technologies, several reference works were consulted, including the RACT/BACT/LAER Clearinghouse (RLBC). From this and other literature sources, a preliminary list of control technologies and their estimated capabilities for potential application to MRYS was developed. However, as discussed in the introduction, Minnkota already has ASOFA and SNCR systems installed on both units to achieve 30-day rolling average removal rates of 60% and 59% on Unit 1 and Unit 2, respectively. Thus, the control technologies included in the RHCT analysis either meet this minimum level of control or have more stringent removal efficiency. Table 2-1 contains the results of this effort.

Table 2-1: NO_x Control Technologies Identified for RHCT Analysis

Control Technology	Approximate Annual Control Efficiency*
Selective Catalytic Reduction and ASOFA	90%
Rich Reagent Injection and SNCR and ASOFA	66-68%
Optimized SNCR and ASOFA	60-61%
Existing SNCR* and ASOFA	Baseline 59-60%

*Based on pre SNCR/ASOFA baseline of 0.820/0.817 lb NO_x/MMBtu for Units 1 and 2, respectively.

2.3 Technical Description and Feasibility Analysis

The second step in the RHCT analysis procedure is a technical feasibility analysis of the options identified in Step 1. The RHCT guidelines discuss consideration of two key concepts during this step in the analysis. The two concepts to consider are the “availability” and “applicability” of each control technology. A control technology is considered available, “if it has reached the stage of licensing and commercial availability.” (70 FR 39165) On the contrary, a control technology is not considered available, “if it is in the pilot scale testing stages of development.” (70 FR 39165) When considering a control technology’s applicability, technical judgment must be exercised to determine “if it can reasonably be installed and operated on the source type.” (70 FR 39165) The technical feasibility analysis is presented below for each identified option.

2.3.1 Selective Catalytic Reduction

The lowest NO_x emission levels from coal-fired utility boilers are typically achieved by installing and operating selective catalytic reduction (SCR) technology. In the SCR process, the gas stream is passed through a catalyst bed in the presence of ammonia to reduce NO_x to molecular nitrogen and water. The process is termed “selective” because the ammonia preferentially reacts with the NO_x rather than with the oxygen in the flue gas. A large reactor containing catalyst is used to enhance NO_x reduction and ammonia utilization at lower flue gas temperatures than required by an SNCR system. SCR is usually

applied to flue gas in the 600°F to 750°F temperature range. There are variations in the SCR process for coal-fired boilers that mostly involve locations in the flue gas path where the catalyst is placed in order to promote the desired NO_x emission reduction effect. This technology was reviewed in the previous BART and BACT analysis (2008-2010) and it was concluded by NDDEQ that SCR systems (of all types) are technically infeasible at MRYS. No new information or experience has occurred since 2010 to change the conclusion of this analysis and this technology remains technically infeasible.

2.3.2 Rich Reagent Injection & Selective Non-Catalytic Reduction

Rich Reagent Injection (RRI) has been demonstrated and placed in continuous operation on multiple cyclone boilers. RRI is specifically intended for NO_x emissions control on cyclone boilers. RRI adds dilute urea reagent to the hot boiler gases near the cyclones, which must be devoid of free oxygen in order to avoid oxidation of the urea and formation of additional NO_x. This system is combined with SNCR to further reduce NO_x emissions within the boiler. The ASOFA system would be operated in conjunction with the RRI and SNCR systems. RRI is considered technically feasible under limited conditions for application on the Unit 1 and Unit 2 cyclone boilers at MRYS.

2.3.3 Optimized Selective Non-Catalytic Reduction

Taking into consideration the past operating experience of the existing system and vendor experience since the original installation, there is potential to reduce the emission rate further with enhancements to the existing system. These enhancements could include changing the nozzles on existing lances, replacing the existing lances, and adding lances in new locations. Additionally, allowing for higher ammonia slip rates than originally designed (i.e., 10 ppm vs. 5 ppm) will allow for higher levels of urea injection, which has the potential to further reduce NO_x emission rates. The ASOFA system would be operated in conjunction with the optimized SNCR system. Optimized SNCR is considered technically feasible for application on the Unit 1 and Unit 2 cyclone boilers at MRYS.

2.3.4 Results of Feasibility Analysis

The evaluations of the identified RHCT alternatives following the feasibility analysis are summarized in Table 2-2.

Table 2-2: MRYS RHCT NO_x Control Feasibility Analysis Results

Control Technology	In full-scale service on Existing Utility Boilers	In Service on Other Combustion Sources	Commercially Available	Technically Applicable to MRYS
SCR	Yes	Yes	No*	No
RRI + SNCR	Yes	Yes	Yes	Yes**
Optimized SNCR	Yes	Yes	Yes	Yes
Existing SNCR	Yes	Yes	Yes	Yes

*Not available on cyclone fired units firing North Dakota lignite.

**Under limited operating conditions

2.4 Evaluate the Technically Feasible NO_x Control Options by Effectiveness

The third step in the RHCT analysis procedure is to evaluate the control effectiveness of the technically feasible alternatives. In step 2 of the RHCT analysis, the NO_x control efficiency was reviewed and presented as part of the technical description for each technology. The evaluations of the remaining RHCT alternatives following the feasibility analysis are summarized in Table 2-3. The alternatives are ranked in ‘top down’ descending order according to their annual effectiveness in NO_x control.

Table 2-3: Feasible NO_x Control Technologies Identified for RHCT Analysis

Control Technology	Unit 1 Annual lb/MMBtu	Unit 2 Annual lb/MMBtu
Applied RRI + SNCR/ASOFA	0.28	0.26
Applied Optimized SNCR/ASOFA	0.33	0.32
Existing SNCR/ASOFA	0.332	0.334

The ‘applied’ emission rates identified in Table 2-3 were developed as annual emission rates taking into account vendor supplied information, variations in load, variations in boiler operating conditions, and experience in the long-term variations in effectiveness of boiler NO_x control technologies. The variable quality of mine-mouth lignite coal is responsible for most of the operating variation experienced. The vendor information is based on MRYS unit-specific measured data of boiler temperature and species of NO_x, CO and O₂. This data was mapped and used to perform computational fluid dynamics (CFD) modeling to determine the equipment, approximate injection locations, and subsequent emission rate able to be achieved. The ‘applied’ emission rates take into account that the rates must be continuously achievable on an annual basis including the impacts of changing unit loads, control equipment limitations, and variability in coal quality.

Load variation must be considered because at lower loads the ability to control NO_x is reduced. The RRI and SNCR systems are designed to inject dilute urea into the correct temperature zones in the boiler for NO_x control. The maximum NO_x reductions from both RRI and SNCR systems occur when steady-state

conditions are achieved when the boiler is at or near full load. At all other conditions, the ability to control NO_x can be significantly impacted. RRI operation depends on oxygen-deprived conditions, and without this (such as with one or more cyclones out of service and/or at lower loads), using the RRI system will increase NO_x emissions. Multiple levels of injection are included to introduce reagent into the correct temperature zone at varying unit loads. However, even with multiple injection levels, emission reductions are reduced at lower loads.

MRYs is a mine-mouth plant that utilizes run-of-mine fuel, which results in significant coal quality variability. Within any 30-day period, the plant can, and has, experienced multiple days of lower quality coal that in turn, creates conditions that make NO_x harder to control, increasing emissions and reagent usage rates.

These factors, along with unit-specific vendor information, were considered in developing the ‘applied’ annual evaluation rate. The emission rates stated by vendors are based on stable, steady state operating conditions, and do not reflect the varying conditions that occur over the life of the equipment, or even in a 30-day or annual operating period. An emission rate must account for operating during periods such as the transition period between two planned stable load conditions, and other unplanned operating variations described above.

During normal high load operations at MRYs, the lower portions of the Unit 1 and Unit 2 boiler are in an oxygen deficient, fuel rich environment. These conditions in the boiler reduce the amount of thermal NO_x being produced as the fuel is combusted. These are the conditions required for optimal use of RRI. As the stoichiometric ratio (oxygen to fuel ratio) in the lower portion of the boiler increases, the performance of a RRI system decreases, with the urea becoming oxidized to create additional NO_x in the presence of oxygen. Several operating conditions can cause lower boiler stoichiometric ratio to increase. Some of these conditions, which are frequently experienced at MRYs, are discussed below:

- Cyclone(s) out of service - Both Unit 1 and Unit 2 boilers are designed to operate with one cyclone out of service and still achieve full load. It is not unusual for single cyclones to be out of service for routine maintenance. Air leaking through the combustion air dampers of an out-of-service cyclone will increase NO_x formation due to addition of oxygen in the fuel-rich zone.
- Main fuel oil in service – Due to variations in coal quality, cyclone(s) may become fouled, meaning that insufficient temperature exists for the slag to flow properly from the cyclone. During these times, it becomes necessary to co-burn fuel oil in the fouled cyclone(s), which

results in increased oxygen in the fuel-rich zone and the formation of additional NO_x. When main fuel oil is in service, the ASOFA system for the cyclone(s) is deactivated because it is ineffective. The deactivation of the ASOFA for the cyclone(s) will increase the stoichiometric ratio in the lower boiler.

- Fuel Variability - With the variability of the coal that is being combusted, the carbon content of the coal also changes. Because the carbon content of the fuel is not known in real-time, the oxygen to fuel carbon ratio continuously changes as the coal composition naturally varies with deliveries from the mine.

As described above, the ‘applied’ annual emission rates established in Table 2-3, for both the RRI + SNCR/ASOFA and Optimized SNCR/ASOFA control technologies, have been determined based on MRYS unit-specific operations and represent annual average emission rates. Note that these projected emission rates do not equate to achievable annual emission permit limits, however.

2.5 Evaluation of Impacts for Feasible NO_x Controls

Step four in the RHCT analysis procedure is the impact analysis. The draft Guidelines (81 FR 44608) lists four factors to be considered in the impact analysis.

- The costs of compliance
- The time required for compliance
- The energy and non-air quality environmental impacts of compliance
- The remaining useful life of the source

Three of the four impacts required by the RHCT Guidelines are discussed in the following sections. The remaining useful life of the source was determined to be greater than the project life definition in the EPA’s OAQPS Control Cost Manual (EPA/453/B-96-001) and thus had no impact on the RHCT determination for MRYS.

2.5.1 Cost Estimates

The following sections evaluate the top two ranked NO_x control options on Unit 1 and Unit 2: replacing the existing SNCR systems with new RRI + SNCR systems and optimizing the existing SNCR systems (with both units maintaining the existing ASOFA systems). Cost estimates for the RRI + SNCR control technology were developed based on proposals from an RRI + SNCR vendor, and installation estimates were based upon Burns & McDonnell’s in-house experience for additional water treatment, compressed air, balance of plant (BOP) piping, access, and installation. The RRI + SNCR vendor utilized CFD

modeling results completed by another vendor as well as conducted on-site data measurement of boiler temperature and species of NO_x, CO and O₂. The measured data was mapped and used to perform additional CFD modeling to determine the equipment and optimum injection locations. The data collected by these vendors and the proposal of the RRI + SNCR technology vendor provide good assurance that the application of these technologies, and their associated costs, are well understood for the boilers at MRYS. Economic information utilized as inputs to the model are provided in Table 1-3.

2.5.1.1 RRI + SNCR Capital Cost Estimate

The vendor equipment cost estimate for the RRI + SNCR system is based on the vendor proposal and includes new RRI injectors and associated equipment as well as equipment necessary to modify the existing SNCR system. A proposal from the vendor has been submitted to NDDEQ under separate cover to protect confidential business information. The remaining capital cost estimate includes installation of the vendor equipment, supply and installation of necessary equipment access, and BOP costs.

Because boiler testing, data from CFD modeling, and detailed RRI injection analysis was performed by the vendors as part of the RRI + SNCR system evaluation, it is known that the necessary injection locations are not in easily accessible locations on either unit. Because of the detailed evaluation by the vendor, the proposed system is specific to MRYS and identified the need for significant BOP modifications. The BOP design accounted for the new recommended RRI + SNCR injection locations by including: new platforms and stairs to access the new injection elevations/locations; significant new piping for increased urea, cooling water, dilution water and atomization air; expansion of the microfiltration and reverse osmosis water system due to the increased dilution water usage; and supply and installation of the boiler bent tube openings for the new RRI + SNCR injectors, including the necessary boiler scaffolding. Appendix A includes a breakdown of major cost categories.

The NO_x control system cost (Table 2-4) is representative of a typical furnish and erect contract.

Table 2-4: Capital Cost Estimate for MRYS Unit 1 & 2 RRI + SNCR System

DIRECT COSTS	Unit 1 Estimated Cost (\$)	Unit 2 Estimated Cost (\$)
RRI and SNCR System		
Equipment Cost	\$4,283,000	\$5,507,000
BOP Costs		
Mechanical Contract	\$1,611,000	\$4,709,000
Foundations and Steel	\$559,000	\$900,000
Electrical and Controls	\$131,000	\$179,000
BOP Total Direct Cost	\$2,301,000	\$5,788,000
Total Direct Cost	\$6,584,000	\$11,295,000
INDIRECT COSTS		
Engineering 10% of DC	\$647,000	\$1,129,000
Escalation	Not Included	Not Included
Indirect Cost Subtotal	\$647,000	\$1,129,000
Contingency (20% of DC)	\$723,000	\$1,242,000
Prime Contractor's Fee (3% of DC)	\$557,000	\$957,000
Total Capital Requirement	\$8,511,000	\$14,623,000

The total estimated capital cost estimate to upgrade the existing Unit 1 SNCR system to a RRI + SNCR system is \$8,511,000, or \$33.1/kW. The total estimated capital cost estimate to upgrade the existing Unit 2 SNCR system to a RRI + SNCR system is \$14,623,000, or \$30.7/kW.

2.5.1.2 Optimized SNCR Capital Cost Estimate

The vendor equipment cost estimate for optimizing the SNCR system is based on the vendor proposal and includes equipment necessary to modify the existing SNCR system. Because of the detailed evaluation by the vendor, the proposed system is specific to the MRYS and identified the need for additional modifications. The design accounted for the new recommended SNCR injection locations by including the supply and installation of the boiler bent tube openings for the new SNCR injectors including the necessary boiler work platforms. The NO_x control system cost (Table 2-5) is representative of a typical furnish and erect contract. Appendix B includes a breakdown of major cost categories.

Table 2-5: Capital Cost Estimate for MRYS Unit 1 & 2 Optimized SNCR System

	Unit 1 Estimated Cost (\$)	Unit 2 Estimated Cost (\$)
DIRECT COSTS		
Optimized SNCR System		
Equipment Cost	\$1,238,000	\$1,265,000
BOP Costs		
Mechanical Contract	\$321,000	\$958,000
Foundations and Steel	\$259,000	\$409,000
Electrical and Controls	\$38,000	\$48,000
BOP Total Direct Cost	\$618,000	\$1,415,000
Total Direct Cost	\$1,857,000	\$2,680,000
INDIRECT COSTS		
Engineering 10% of DC	\$183,000	\$268,000
Escalation	Not Included	Not Included
Indirect Cost Subtotal	\$183,000	\$268,000
Contingency (20% of DC)	\$204,000	\$295,000
Prime Contractor's Fee (3% of DC)	\$157,000	\$227,000
Total Capital Requirement	\$2,400,000	\$3,470,000

The total estimated capital cost estimate to optimize the Unit 1 SNCR system is \$2,400,000 or \$9.3/kW.

The total estimated capital cost estimate to optimize the Unit 2 SNCR system is \$3,470,000 or \$7.3/kW.

2.5.1.3 RRI + SNCR O&M Cost Estimate

The annual O&M costs are comprised of fixed costs (maintenance and labor) and variable cost (consumables). The fixed costs include operating labor, administrative and support labor, and the maintenance material and labor costs. No change in administrative, support and operating labor cost was assumed. The maintenance material and labor cost is estimated at 3% of the system direct capital costs in Table 2-4. Table 2-6 summarizes the O&M cost estimates for the RRI + SNCR systems.

Variable costs include reagent, cooling water, dilution water, auxiliary power costs and the loss of electrical generation revenues. The estimated annual costs for these consumables are the estimated change from the baseline conditions based on vendor provided consumption rates, unit operating assumptions and the unit cost information provided in Table 1-3. The costs associated with loss of electrical generation capacity (i.e. revenue lost) are because of the significant quantity of urea and water that is introduced to the boiler with increased dilute urea injection. This additional urea and water is evaporated and

negatively impacts the unit efficiency. Since the assumption of this RHCT analysis is that heat input is the same in the baseline case as for the future control alternatives, the loss in unit efficiency equates to a decrease in generation. While lost electricity sales revenues are not in actuality an O&M expense, they represent an opportunity cost of installing RRI + SNCR and are thus important to include for the purposes of this analysis.

Table 2-6: O&M Cost Estimate for MRYS Unit 1 & 2 RRI + SNCR System

Fixed Costs	Unit 1	Unit 2
Operating Labor	\$0	\$0
Admin and Support labor	\$0	\$0
Maintenance Material and Labor	\$47,000	\$54,000
Total Fixed O&M Costs	\$47,000	\$54,000
Variable Costs		
Urea Reagent	\$4,522,000	\$4,590,000
Water	\$209,000	\$471,000
Auxiliary Power	\$45,000	\$44,000
Lost Generation	\$469,000	\$1,119,000
Total Variable O&M Costs	\$5,245,000	\$6,224,000
Total Annual O&M Costs	\$5,292,000	\$6,278,000
Net Annual O&M Cost (\$/MWh)	2.94	1.91

O&M Cost represent costs above the baseline (existing system)

2.5.1.4 Optimized SNCR O&M Cost Estimate

The annual O&M costs are comprised of fixed costs (maintenance and labor) and variable cost (consumables). The fixed costs include operating labor, administrative and support labor and the maintenance material and labor costs. The maintenance material and labor cost is estimated at 3% of the new direct capital costs in Table 2-5. No change in administrative, support and operating labor cost was assumed. Table 2-7 summarizes the O&M cost estimates for the Optimized SNCR system.

Variable costs include reagent, dilution water, auxiliary power costs and loss of electrical generation revenues. The estimated annual costs for these consumables are the estimated change from the baseline conditions based on vendor provided consumption rates, unit operating assumptions and the unit cost information provided in Table 1-3. The costs associated with loss of electrical generation capacity (i.e. revenue lost) are because of the significant quantity of urea and water that is introduced to the boiler with increased urea injection. This additional urea and water is evaporated and negatively impacts the unit efficiency. Since the assumption of this RHCT analysis is that heat input is the same in the baseline case as for the future control alternatives, the loss in unit efficiency equates to a decrease in power generation.

Table 2-7: O&M Cost Estimate for MRYS Unit 1 & 2 Optimized SNCR System

Fixed Costs	Unit 1	Unit 2
Operating Labor	\$0	\$0
Admin and Support labor	\$0	\$0
Maintenance Material and Labor	\$35,000	\$36,000
Total Fixed O&M Costs	\$35,000	\$36,000
Variable Costs		
Urea Reagent	\$1,661,000	\$909,000
Water	\$19,000	\$116,000
Auxiliary Power	\$23,000	\$22,000
Lost Generation	\$95,000	\$414,000
Total Variable O&M Costs	\$1,798,000	\$1,461,000
Total Annual O&M Costs	\$1,833,000	\$1,497,000
Net Annual O&M Cost (\$/MWh)	1.02	0.46

O&M Cost represent costs above the baseline (existing system)

2.5.1.5 Annualized Total Cost

In order to effectively compare the cost of installing, operating and maintaining the NO_x control systems, capital and O&M costs can be evaluated on an annualized basis.

The Annualized Total Cost (ATC) for NO_x control systems was calculated based on a 20-year project life and is presented in Table 2-8 and Table 2-9, for Unit 1 and Unit 2, respectively, along with the emissions reduction, resultant emissions rate and the Unit Control Cost. No salvage value was assumed at the end of the service life. The Unit Control Cost is the ATC divided by the annual tons of NO_x emissions that would be controlled by implementation of the respective control technology. The ATC and Unit Control Cost are used to evaluate the control technologies on a cost effectiveness basis.

Table 2-8: Annualized Total Cost of MRYS Unit 1 NO_x Control Technologies

NO _x Control Alternative	Emission Rate lb/10 ⁶ Btu	Annual Emissions (tpy) ¹	Annual Emission Reduction (tpy) ¹	Installed Capital Cost (\$) ²	Annual O&M Cost (\$)	Annualized Total Cost (\$) ³	Actual Unit Control Cost (\$/ton) ⁴	Incremental Unit Control Cost (\$/ton)
Applied RRI+SNCR/ASOFA	0.28	2,902	539	8,500,000	5,300,000	6,000,000	11,100	7,700
Applied Optimized SNCR/ASOFA	0.33	3,420	21	2,400,000	1,800,000	2,000,000	96,500	
Existing SNCR/ASOFA ⁵	0.332	3,441	Baseline					

1. Based on baseline heat input of 20,726,417 MMBtu/yr
2. All Costs in 2019 dollars.
3. For ATC calculation, Capital Recovery Factor = 0.08368 and first year O&M Cost.
4. Overall control cost is ATC divided by actual annual emissions reduction of each alternative.
5. Baseline emission rate based on average emission rate between 2016-2018.

Table 2-9: Annualized Total Cost of MRYS Unit 2 NO_x Control Technologies

NO _x Control Alternative	Emission Rate lb/10 ⁶ Btu	Annual Emissions (tpy) ¹	Annual Emission Reduction (tpy) ¹	Installed Capital Cost (\$) ²	Annual O&M Cost (\$)	Annualized Total Cost (\$) ³	Actual Unit Control Cost (\$/ton) ⁴	Incremental Unit Control Cost (\$/ton)
Applied RRI+SNCR/ASOFA	0.26	4,466	1271	14,600,000	6,300,000	7,500,000	5,900	5,500
Applied Optimized SNCR/ASOFA	0.32	5,497	240	3,500,000	1,500,000	1,800,000	7,500	
Existing SNCR/ASOFA ⁵	0.334	5,737	Baseline					

1. Based on baseline heat input of 34,354,956 MMBtu/yr
2. All Costs in 2019 dollars.
3. For ATC calculation, Capital Recovery Factor = 0.08368 and first year O&M Cost.
4. Overall control cost is ATC divided by actual annual emissions reduction of each alternative.
5. Baseline emission rate based on average emission rate between 2016-2018.

2.5.1.6 Cost Estimate Conclusion

In the RHCT guidelines, EPA does not provide definition, or even discussion of what Unit Control Costs are considered reasonable or unreasonable. NDDEQ has indicated that costs below \$4,500 per ton may be considered to be reasonable.

The cost analysis portion of the RHCT determination for MRYS Unit 1 and 2 indicates that Actual Unit Control Costs for the top ranked RRI + SNCR for Unit 1 is more than double \$4,500 per ton and the Unit 2 cost is almost \$6,000 per ton. The incremental rate (cost of removal between two options) of controlling NO_x with RRI + SNCR is also over \$4,500 per ton on both Units. From an economic analysis

viewpoint, the RRI+SNCR system, although the top ranked technology, is not an economically feasible NO_x control alternative for either Unit 1 or Unit 2.

The Actual Unit Control Costs for the next top ranked control technology, optimized SNCR system, for Unit 1 is more than an order of magnitude greater than \$4,500 per ton and the Unit 2 cost is over \$7,000 per ton. From an economic analysis viewpoint, the optimized SNCR system is not an economically feasible NO_x control alternative for Unit 1 or Unit 2.

2.5.2 Energy Impacts

The primary energy impact of the RRI + SNCR and Optimized SNCR systems is reduced boiler efficiency due to evaporation of large amounts of dilute urea. For the purposes of this RHCT analysis, it was assumed that the heat input rate (MMBtu/yr) for the baseline and each control technology case were the same. Therefore, no additional coal usage was assumed; rather, it was assumed that a loss of electrical generation capacity would occur for the control cases. However, for the Optimized SNCR for Unit 1, the equivalent of an additional 8 tons of coal per day would be required to evaporate the expected amount of dilute urea to be injected into the boiler. For Optimized SNCR for Unit 2, the equivalent of an additional 34 tons of coal per day would be required to evaporate the expected amount of dilute urea to be injected into the boiler. For the RRI + SNCR for Unit 1, the equivalent of an additional 39 tons of coal per day would be required to evaporate the expected amount of dilute urea to be injected into the boiler. For RRI + SNCR for Unit 2, the equivalent of an additional 94 tons of coal per day would be required to evaporate the expected amount of dilute urea to be injected into the boiler. Increasing heat input to maintain present unit production capacity may have New Source Review, Prevention of Significant Deterioration implications that could add significant cost and permitting considerations. Without a heat input increase, electrical generation would decrease, meaning that generation from another unit, with unknown environmental profile, would be required to make up for the loss.

Other energy impacts include an incremental increase in water consumption due to the need for additional cooling water, and an incremental increase in energy related to providing more compressed air for reagent atomization. Auxiliary power requirements for each of the control technologies are presented in Table 2-10 and Table 2-11 for Unit 1 and Unit 2, respectively.

Table 2-10: Auxiliary Energy Requirement of MRYS Unit 1 NO_x Control Technologies

RHCT Alternative	Energy Demand (kW)	Percent of Nominal Generation
Existing SNCR	200	0.09%
Optimized SNCR	266	0.11%
RRI + SNCR	332	0.14%

Table 2-11: Auxiliary Energy Requirement of MRYS Unit 2 NO_x Control Technologies

RHCT Alternative	Energy Demand (kW)	Percent of Nominal Generation
Existing SNCR	300	0.07%
Optimized SNCR	366	0.08%
RRI + SNCR	432	0.10%

2.5.3 Non-Air Quality Environmental Impacts

The addition of the RRI system to the SNCR system is not expected to significantly impact emissions of CO or volatile organic compounds (VOCs).

Operation of the existing SNCR system creates a small amount of unreacted ammonia to be emitted. In the future, the settings for the new RRI+SNCR or Optimized SNCR system may increase the amount of ammonia slip produced. Higher NO_x reduction performance involves greater amounts of reagent usage and consequently, the increased ammonia slip. This is typically controlled to less than 10 ppmvd, especially when the possible formation of sulfates such as ammonium sulfate [(NH₄)₂SO₄] and ammonium bisulfate [NH₄HSO₄] will be more problematic at higher slip levels. Sulfur trioxide (SO₃) formed during combustion in the boiler can combine with ammonia during passage through the flue gas ductwork to form the sulfates.

Some of the unreacted ammonia (ammonia slip) will be collected with the fly ash in the ESP. Any remaining ammonia slip that is not collected or condensed in the air pollution control system will be collected in the wet scrubber or emitted from the chimney as an aerosol or condensable particulate. Increasing the ammonia slip has the potential to increase atmospheric visibility impairment downwind of the facility compared with a pristine condition. Although the predicted amount of such potential impact from ammonia slip emissions has not been determined, it is expected to be small in comparison with the

significant anticipated reduction in far-field ozone and improvement in atmospheric visibility as a result of the overall NO_x emission reduction.

One mole of carbon dioxide (CO₂) will be created and emitted for every mole of urea injected for reaction with NO_x. The consumption rate of urea will significantly increase with the use of RRI + SNCR or optimized SNCR and thus the CO₂ rate will also increase. However, this is a relatively small increase in the total amount of CO₂ produced as part of the combustion of carbon-based fossil fuel in the form of lignite.

Delivery of the urea reagent to the MRYS and storage of aqueous urea reagent on-site creates the potential for accidents, leaks, and subsequent releases to air, ground, and surface water immediately surrounding the facility. Urea is much less volatile than anhydrous or aqueous ammonia, and these risks are expected to be manageable.

Increased dilution water and urea usage rates will require the production of greater volumes of microfiltration/reverse osmosis (MF/RO) and condensate quality water for dilution of concentrated urea deliveries and injection into the boiler. The production of MF/RO and condensate quality water results in a discharge of a concentrated brine solution, which is ultimately discharged under the requirements of the MRYS facility NDPDES permit. This waste stream typically represents 20% of the RO product volume produced. This would result in millions of gallons of additional water treatment wastewaters being discharged from the MRYS facility on an annual basis.

2.5.4 NO_x Control Technology Evaluation Conclusion

The energy impacts of a new RRI + SNCR system or an optimized SNCR system are only incrementally higher than the existing system. These incremental increases are acceptable.

The non-air quality impacts of a new RRI + SNCR system or an optimized SNCR system are very similar to the impacts of the existing SNCR system. There will be an increase in the ammonia carry over from the systems but a majority of that will be captured in the wet FGD system. There will be insignificant increases in CO₂ due to the increased consumption of urea. There will be additional RO/condensate waste due to the increase in demand from the systems. All of these non-air quality impacts are considered acceptable.

The average control cost to add an RRI system or to optimize the SNCR system is above \$4,500 per ton. This evaluation results in the determination that maintaining operation of the existing SNCR system is the RHCT top ranked control technology.

This evaluation determined maintaining the existing annual emission rates of 0.332 lb NO_x/MMBtu and 0.334 lb NO_x/MMBtu for Unit 1 and Unit 2, respectively, should be modeled by WRAP as appropriate annual emission rates for the Step 5 review. Maintaining the existing 30-day emission limits of 0.36 lb NO_x/MMBtu and 0.35 lb NO_x/MMBtu for Unit 1 and Unit 2, respectively, are appropriate permit limits.

The emission rates in this report are for WRAP modeling and are not proposed permit emission limit. As EPA has indicated, the Regional Haze Roadmap may be updated, and the results of the WRAP modeling will provide new information to be considered. Minnkota reserves the right to modify the four factor analysis once the Regional Haze Roadmap, any additional guidance and the results of the WRAP modeling are available. In addition, Minnkota reserves the right to conduct a 5th factor analysis based on visibility modeling once the results of the WRAP modeling are available.

This analysis is provided to assist the NDDEQ in the WRAP modeling and is not intended to serve as an agreement by Minnkota to any changes in permitted emission limits or permit conditions.

3.0 SO₂ RHCT EVALUATION

The RHCT determination process has five predefined steps as described in Section 1. In this section, steps 1 through 4 of the RHCT determination for MRYS are described for SO₂ and a presentation is made of the results. Potentially applicable SO₂ control technologies are first identified. A brief description of the processes and their capabilities are reviewed for availability and feasibility. Subsequently, those available technologies deemed feasible for retrofit application are ranked according to nominal SO₂ control capability. The impacts analysis then reviews the estimated capital and O&M costs for each alternative. Following the cost determination, the energy impacts and non-air quality impacts are reviewed for each technology. The impact based on the remaining useful life of the source is reviewed as part of the cost analysis. The results of the impact analyses are tabulated and potential RHCT options are listed.

3.1 SO₂ Evaluation Basis

MRYS Unit 1 includes a B&W steam generator installed in 1970. The steam generator is a lignite-fired boiler with multiple cyclone-furnaces installed in parallel using balanced-draft and natural circulation. The boiler is fired by seven ten-foot diameter cyclone furnaces, arranged “three over four” across the front wall of the lower boiler. The unit has a tubular air heater installed between the boiler and the flue gas ductwork leading to the ESP. Unit 1’s boiler serves a turbine generator with a nameplate rating of 257 MW⁵. The Unit 1 boiler at MRYS includes a unique coal conditioning system (drying, crushing, and feeding) for each cyclone furnace specifically designed to aid in proper combustion of the lignite fuel. Lignite fuel is the sole solid fuel for the plant and is supplied from a mine located adjacent to the site. The baseline emission rate of the Unit 1 boiler using the existing wet FGD system is 0.0739 lb SO₂/MMBtu, as described previously in Section 1.1.5.

MRYS Unit 2 is a B&W steam generator installed in 1977. The steam generator is a lignite-fired boiler with multiple cyclone-furnaces installed in parallel using balanced-draft and natural circulation assisted with circulation pumps. The boiler is fired by twelve ten-foot diameter cyclone furnaces, arranged “three over three” across the front and rear walls of the lower boiler. The unit has a tubular air heater installed between the boiler and the flue gas ductwork leading to the ESP. Unit 2’s boiler serves a turbine-generator with a nameplate rating of 477 MW⁶. The Unit 2 boiler at MRYS includes a unique coal conditioning system (drying, crushing, and feeding) for each cyclone furnace specifically designed to aid

⁵ Ibid EPA’s eGRID database; April, 2003.

⁶ Ibid EPA’s eGRID database; April, 2003.

in proper combustion of the lignite fuel. Lignite fuel is the sole solid fuel for the plant and is supplied from a mine located adjacent to the site. The baseline emission rate of the Unit 2 boiler using the existing wet FGD system is 0.126 lb SO₂/MMBtu, as described previously in Section 1.1.5.

3.2 Identification of Retrofit SO₂ Control Technologies

The initial step in the RHCT determination is the identification of retrofit SO₂ control technologies. In order to identify the applicable SO₂ control technologies, several reference works were consulted, including “Controlling SO₂ Emissions: A Review of Technologies (EPA-600/R-00-093, October 2000) and the RACT/BACT/LAER Clearinghouse (RLBC). From these and other literature sources, a preliminary list of control technologies and their estimated capabilities for potential application to MRYS was developed. However, Minnkota already has wet FGD systems installed on both units to achieve annual average removal rates of 96.8% and 94.9% on Unit 1 and 2, respectively (based on 3-year average baseline emissions). Additionally, Unit 2 complies with a 0.15 lb/MMBtu 30-day rolling average emission limit. Thus, the control technologies included in the RHCT analysis either meet this minimum level of control or have more stringent removal efficiency. Table 3-1 contains the results of this effort.

Table 3-1: SO₂ Control Technologies Identified for RHCT Analysis

Control Technology	Approximate Annual Control Efficiency
ReACT Scrubber	92-98%
New Wet FGD	98%
Modify Existing Wet FGD	96-98%
Circulating Semi-Dry FGD	90-97%
Semi-Dry FGD	90-95%

3.3 Technical Description and Feasibility Analysis

The second step in the RHCT analysis procedure is a technical feasibility analysis of the options identified in Step 1. The RHCT guidelines, which reference the prior BART Guidelines, discuss consideration of two key concepts during this step in the analysis. The two concepts to consider are the “availability” and “applicability” of each control technology. A control technology is considered available “if it has reached the stage of licensing and commercial availability” (70 FR 39165). On the contrary, a control technology is not considered available “if it is in the pilot scale testing stages of development” (70 FR 39165). When considering a source’s applicability, technical judgment must be exercised to determine “if it can reasonably be installed and operated on the source type” (70 FR 39165). The technical and feasibility analysis is presented below for each identified option.

3.3.1 Wet Flue Gas Desulfurization

Wet FGD technology utilizing lime or limestone as the reagent is commonly applied to coal-fired boilers. Wet FGD utilizes an absorber, such as an open spray tower or a spray tower with a perforated plate contactor, to expose flue gas to the neutralizing slurry. Absorbed SO₂ is converted to calcium sulfite and then may be oxidized to calcium sulfate dihydrate (gypsum) which is filtered from the scrubber solution and either disposed of in a permitted disposal facility, or possibly sold for either wallboard or cement production. Lime is utilized as the reagent in the wet FGD technology analysis because the plant currently uses lime in the FGD processes and has existing lime reagent preparation equipment. Lime, rather than limestone, is used at the plant because it is the most cost-effective reagent to truck to the plant. The MRYS is not equipped with rail service.

An alternative reagent to lime or limestone is ammonia. The scrubbing technology is similar to other wet FGD systems; however, the byproduct handling is significantly different. The advantage of utilizing ammonia is the production of a high value fertilizer byproduct (ammonium sulfate). This byproduct is a commodity that can be sold worldwide all year. The byproduct, if sold in liquid form, may not require any treatment and limited handling. A potential disadvantage of utilizing ammonia reagent is if the byproduct is not sold in liquid form, it could require significant handling/treatment depending on the final product requirements (delivery, target clients, etc). This handling/treatment could include some or all of the following steps; concentration, crystallization, drying, prilling and storage. As fertilizer demand near MRYS is seasonal, the product will need to be shipped to other parts of the United States or the world market.

Historically, wet FGD systems have operated with SO₂ control efficiency anywhere from 70% to 98%. New coal-fired power plant SO₂ control projects have achieved coal to chimney SO₂ control efficiency of ≥ 99 percent. However, considering a reasonable degree of margin is appropriate to allow for continuous compliance including upsets, fuel variability, and operational variability, 98% removal is evaluated as an appropriate removal rate for a new state of the art scrubber.

For the purposes of this analysis, new wet FGD performance was evaluated at 98% SO₂ removal. Due to the relative ages of Unit 1 and Unit 2 scrubbers, a new wet scrubber was considered only for Unit 2, as the Unit 1 wet scrubber was placed in service relatively recently, in 2011. Based on the ability of a new wet FGD system to achieve 98% percent SO₂ removal efficiency and considering the commercial availability and applicability, a new wet FGD system was found to be a technically feasible RHCT alternative for MRYS Unit 2 SO₂ emission control.

This report also evaluates the modification of the existing wet FGD process currently operating on Unit 1 and Unit 2 as a possible RHCT alternative. The original equipment manufacturer (OEM) of the Unit 1 scrubber was engaged to evaluate modifications required to increase the removal efficiency of the existing wet FGD processes. The same OEM has previously studied upgrading the Unit 2 scrubber to achieve higher removal efficiency, and was engaged to update and confirm the results of that study. Upgrades evaluated include increasing the liquid-to-gas ratio, installation of new types of spray nozzles, running additional pumps, and adjusting the operating conditions of the scrubber. The OEM study evaluated the scrubbers based on the highest sulfur coal (3.16 lb SO₂/MMBtu) identified by core samples collected and analyzed by the mine that supplies MRYS. The high sulfur fuel is utilized in this evaluation to ensure the updated scrubber is capable of the necessary long-term fuel flexibility associated with a mine mouth plant. The removal rates referenced in the confidential vendor proposal (submitted separately under confidentiality) are coal to chimney short term (test period) removal rates reflective of vendor determined performance. This RHCT evaluation, however, has applied selected removal rates across the scrubber.

The selected rates applied across the scrubber is considered a reasonable balance of the difference between: the baseline scrubber inlet SO₂ and the studied sulfur content of the coal, consideration of the need for margin between a guarantee and long term continuously achievable performance, and long term (annual performance) basis of this evaluation. Optimizing Unit 1 is assumed to increase removal across the scrubber to 97.4% by increasing stoichiometry (Ca/S) to 1.025. Upgrading Unit 2 is assumed to increase removal across the scrubber to 97.6% utilizing the recommended nozzle changes, additional spray header, and increasing the stoichiometry to 1.020. MRYS did not increase the stoichiometry in Unit 2 to the same level as Unit 1 because MRYS experience on Unit 2 is that operating at higher pH (associated with higher stoichiometry) will cause increased scaling and plugging of the suction screens to the spray recycle pumps that will reduce the liquid to gas ratios, and hence lower SO₂ removal.

3.3.2 Semi-Dry Flue Gas Desulfurization

As an alternative to wet FGD technology, the control of SO₂ emissions can be accomplished using semi-dry FGD technology. The most common semi-dry FGD system is the lime Spray Dryer Absorber (SDA) using a fabric filter for downstream particulate collection. There are several variations of the semi-dry process in use today. Two other variations, the Flash Dryer Absorber (FDA) and Circulating Dry Scrubber (CDS) are similar in nature. They primarily differ by the type of reactor vessel used, the method in which water and lime are introduced into the reactor and the degree of solids recycling. This section addresses the SDA process and the CDS process.

No SDA process has clearly demonstrated the ability to achieve SO₂ removal levels similar to wet FGD systems in the U.S. The application of high SO₂ removal SDA system for high sulfur coal have been limited in the industry due to multiple factors. For purposes of completeness an SDA system is assumed to be able to achieve 93% removal in this application.

The CDS system can increase the lime injection rate independent of the water injection and higher removal rates can be achieved. The CDS system removal is assumed to be equivalent to the retrofit wet FGD system achieving 95-97% removal.

3.3.3 ReACT Dry Scrubbing Process

ReACT (Regenerative Activated Coke Technology) is a multipollutant control system that utilizes activated coke to remove SO₂, NO_x and mercury. The process is divided into three main processes: 1) adsorption, 2) regeneration, and 3) recovery. In the first step, ammonia is injected into the flue gas and the flue gas is passed through an adsorber filled with a moving bed of activated coke pellets where the SO₂ and mercury are adsorbed and the NO_x is reduced to N₂. In the second step, the activated coke pellets are transferred to a second vessel to be regenerated for recycle/reuse through thermal desorption. The captured mercury is concentrated in the lower portion of the regenerator vessel. The resulting gas from the regeneration step is a concentrated stream of SO₂ that must be further treated in a separate acid recovery plant to produce a sellable sulfuric acid byproduct. Sulfuric acid is a worldwide commodity that, with access, can be sold year-round. This ReACT process is installed and operating on multiple low sulfur coal fired units achieving ≥99% SO₂ removal. Burns & McDonnell contacted the supplier of the ReACT process and discussed the application of the technology to an application like MRYS. It was determined that MRYS is ‘not a good application’ for the technology, however, the technology could be applied and would work. Factors in this application at MRYS that would impact performance and cost of ReACT include that the inlet temperature is too high, higher oxidation of the activated coke can be expected, and the sulfuric acid production rates would be very high. This technology is still considered a viable alternative and previous ReACT pilot tests on high sulfur coals have shown ReACT can achieve 92-98% SO₂ removal rates.

3.3.4 Results of Feasibility Analysis

The evaluations of the identified RHCT alternatives following the feasibility analysis are summarized in Table 3-2.

Table 3-2: MRYS RHCT SO₂ Control Feasibility Analysis Results

Control Technology	In full-scale service on Existing Utility Boilers	In Service on Other Combustion Sources	Commercially Available	Technically Applicable To MRYS
ReACT Scrubber	Yes	Yes	Yes	Yes
Wet FGD	Yes	Yes	Yes	Yes
CDS Dry FGD	Yes	Yes	Yes	Yes
SDA Dry FGD	Yes	Yes	Yes	Yes

3.4 Evaluate Technically Feasible SO₂ Control Options by Effectiveness

The third step in the RHCT analysis procedure is to evaluate the control effectiveness of the technically feasible alternatives. During the feasibility determination in step 2 of the RHCT analysis, the SO₂ control efficiency was reviewed and presented as part of the technical description for each technology. The evaluations of the remaining RHCT alternatives following the feasibility analysis are summarized in Table 3-3. The alternatives are ranked in descending order according to their effectiveness in SO₂ control. The control efficiencies listed in Table 3-3 are representative of annual average removal rates and do not represent a permit limit that would be continuously achievable over a 30-day rolling average.

Table 3-3: Feasible SO₂ Control Technologies Identified for RHCT Analysis

Control Technology	Unit 1¹	Unit 2¹
New Wet FGD	Not Reviewed ²	98% Control
ReACT	98% Control	98% Control
Retrofit Existing Wet FGD	97.4% Control	97.6% Control
CDS Semi-Dry FGD	NA ³	NA ³
SDA FGD	NA ³	NA ³

1. Control rates are reflective of conservative (high) annual removal rates and do not reflect maintainable/guaranteed 30-day rates.
2. Existing system was installed in 2011, so replacement with a like-kind system was not reviewed.
3. SDA and semi-dry FGDs are not evaluated for Unit 1 or 2 because the existing wet FGD can be used to achieve equivalent removal efficiency while using existing equipment.

3.5 Evaluation of Impacts for Feasible SO₂ Controls

Step four in the RHCT analysis procedure is the impact analysis. The draft Guidelines (81 FR 44608) lists four factors to be considered in the impact analysis.

- The costs of compliance;
- The time required for compliance;
- Energy and non-air quality environmental impacts of compliance
- The remaining useful life of the source.

Three of the four impacts required by the RHCT Guidelines are discussed in the following sections. The remaining useful life of the source was determined to be greater than the project life definition in the

EPA's OAQPS Control Cost Manual (EPA/453/B-96-001) and thus had no impact on the RHCT determination for MRYS.

Unlike the Best Available Retrofit Technology (BART) evaluation performed in the last round for the RHCT evaluation, the technologies in the second implementation period are evaluated on a 'Top Down' basis similar to a Best Available Control Technology (BACT) approach. Where multiple technologies achieve similar removal rates, a single technology is evaluated to represent that level of performance. The top rated SO₂ removal rate is 98% removal and can be achieved by replacing the existing wet FGD system with either a new wet FGD system or a ReACT system. As a wet FGD system is a well demonstrated technology for high sulfur fuel and ReACT has only been applied on low sulfur fuel, this evaluation will focus on the new wet FGD option to evaluate the top-rated option. As shown in Table 3-3, ReACT is not expected to have better performance than wet FGD in operating conditions encountered at MRYS.

3.5.1 Cost Evaluation

The following sections evaluate the top two ranked control options for Unit 2, replacing the existing wet FGD system with a new wet FGD system, and upgrading the Unit 2 scrubber. A new wet FGD was not considered for Unit 1, as the existing wet FGD began operations in 2011 as part of the previous BART/BACT analysis and is within the previously evaluated useful life. The top ranked control option for Unit 1, modify the existing wet FGD, is evaluated.

3.5.1.1 New Wet FGD Capital Cost Estimate

Cost estimates for the new wet FGD SO₂ control technologies were completed utilizing the 'IPM Model – Updates to Cost and Performance for APC Technologies Wet FGD Cost Development Methodology' available from the U.S. Environmental Protection Agency and supplemented with engineering estimates based upon Burns & McDonnell's in-house experience. The IPM Model Update is a formula-based report that was specifically developed to estimate the cost of wet FGD technologies for utility power plants. The report was prepared for the EPA in January 2017. The report is available for download from the U.S. EPA website⁷.

As a conservative (lowest cost) approach, this evaluation only considered the 'Absorber Island' portion of the new scrubber cost at a retrofit factor of 1.0 and supplemented this with engineering estimates for new duct work, connecting piping and space modifications required to fit the absorber. This approach

⁷ www.epa.gov/airmarkets/documentation-epas-power-sector-modeling-platform-v6

assumes all of the existing balance of plant (BOP) systems are capable of supporting the new system with no upgrades. Further, it is assumed there is no change in operating staff and only a proportional change in the variable operating cost. These conservative assumptions minimize the overall project cost resulting in a conservatively low dollars per ton control cost.

For the addition of a new wet FGD, Unit 2 will require new ductwork to connect to the new wet FGD system, modifications to the coal pile to create space for the new system and electrical replacement/ upgrades for the new scrubber or a significantly extended outage to allow for the existing wet FGD system to be shut down while the new system is tied in, commissioned and started up. The SO₂ control system cost is representative of a typical furnish and erect contract by a wet FGD system supplier. Economic information utilized as input into the model is given in Table 1-3. The results of the capital cost estimates are given in Table 3-4.

Table 3-4: Capital Cost Estimate for MRYS Unit 2 New Wet Lime FGD System

DIRECT COSTS	Unit 2 Estimated Cost (\$)
New FGD Absorber	
FGD Island Equipment Cost	\$51,586,000
BOP Costs	
Mechanical Contract	\$54,000,000
Foundations and Steel	\$4,461,000
BOP Total Direct Cost	\$58,461,000
Total Direct Cost	\$110,047,000
INDIRECT COSTS	
Engineering 10% of DC	\$11,005,000
Escalation	Not Included
Indirect Cost Subtotal	\$11,005,000
Contingency (20% of DC)	\$12,105,000
Prime Contractor's Fee (3% of DC)	\$9,321,000
Owners Cost	Not Included
Total Capital Requirement	\$142,478,000

The total estimated capital cost estimate for a complete new wet FGD absorber is \$142,478,000 or \$299/kW.

3.5.1.2 Wet FGD Modification Capital Cost Estimate

Cost estimates for retrofitting the existing wet FGD systems were based on the equipment modification and associated pricing provided by the OEM (provided separately under confidentiality) and supplemented with engineering estimates for installation based upon Burns & McDonnell's in-house experience.

This evaluation assumes all of the existing BOP systems are capable of supporting the new system with no further upgrades. Further, it is assumed there is no change in operating staff and only a proportional change in the variable operating cost. These conservative assumptions minimize the overall project cost resulting in a conservatively low dollars per ton control cost.

The capital cost estimate for the Unit 1 wet FGD system modification includes the OEM recommendation to replace three out of the four recirculation pump motors to increase the liquid to gas ratio in the scrubber. During this investigation, the existing electrical system and foundation associated with the pump was reviewed and is believed to be sufficient to support this upgrade with no further modifications.

The capital cost estimate for the Unit 2 wet FGD system modification includes the OEM recommendation to replace all of the absorber spray nozzles with dual flow nozzles. The OEM did not recommend upgrading the pumps on Unit 2 due to velocity limitations in the riser pipe and headers and did not recommend upgrading the riser headers and spray headers to accommodate more flow as these upgrades could compromise or complicate the conditions of the existing towers. The results of the capital cost estimates for the FGD system modifications are given in Table 3-5.

Table 3-5: Capital Cost Estimate for MRYS Unit 1 Wet FGD System Modification

DIRECT COSTS	Unit 1 Estimated Cost (\$)	Unit 2 Estimated Cost (\$)
Modified FGD System		
Equipment Cost	\$569,000	\$1,011,000
BOP Costs		
Mechanical Contract	\$0	\$280,000
Electrical and Controls	\$16,000	\$0
BOP Total Direct Cost	\$16,000	\$280,000
Total Direct Cost	\$585,000	\$1,291,000
INDIRECT COSTS		
Engineering 10% of DC	\$58,000	\$129,000
Escalation	Not Included	Not Included
Indirect Cost Subtotal	\$58,000	\$129,000
Contingency (20% of DC)	\$64,000	\$142,000
Prime Contractor's Fee (3% of DC)	\$50,000	\$109,000
Total Capital Requirement	\$757,000	\$1,671,000

The total estimated capital cost for upgrades to the Unit 1 wet FGD system is \$757,000, or \$3.00/kW.

The total estimated capital cost for upgrades to the Unit 2 wet FGD system is \$1,671,000, or \$3.50/kW.

3.5.1.3 New Wet FGD O&M Cost Estimate

The annual O&M costs are comprised of fixed costs (maintenance and labor) and variable cost (consumables). The O&M costs are evaluated as additional costs beyond the existing wet FGD system as the current costs are part of the baseline operating conditions. The operating labor cost of a new system is not expected to be significantly different than the existing system over the life of the equipment. No additional operating labor has been assumed.

Variable costs include reagent, makeup water, FGD byproduct disposal and auxiliary power costs. The estimated annual costs for these consumables are based on the incremental consumption rates change between the existing removal rate and the new removal rate and the unit cost information provided in Table 1-3. Table 3-6 provides the O&M cost estimate.

Table 3-6: O&M Cost Estimate for a New MRYS Unit 2 Wet Lime FGD System

Fixed Costs		Unit 2
Operating Labor		\$0
Admin and Support labor		\$0
Maintenance Material and Labor		\$3,301,000
Total Fixed O&M Costs		\$3,301,000
Variable Costs		
Lime Reagent		\$21,000
Byproduct Disposal		\$233,000
Auxiliary Power		\$727,000
Total Variable O&M Costs		\$981,000
Total Annual O&M Costs		\$4,282,000
Net Annual O&M Cost (\$/MWh)		1.30

3.5.1.4 Wet FGD Modification O&M Cost Estimate

The annual O&M costs are comprised of fixed costs (maintenance and labor) and variable cost (consumables). The O&M costs are evaluated as additional costs beyond the existing wet FGD system as the current costs are part of the baseline operating conditions. The operating labor cost of a new system is not expected to be significantly different than the existing system over the life of the equipment. No additional operating labor has been assumed.

Variable costs include reagent, FGD byproduct disposal and auxiliary power costs. The estimated annual costs for these consumables are based on the incremental consumption rates change between the existing removal rate and the new removal rate and the unit cost information provided in Table 1-3. Table 3-7 provides the O&M cost estimate.

Table 3-7: O&M Cost Estimate for MRYS Unit 1 and 2 Wet Lime FGD System Modification

Fixed Costs	Unit 1	Unit 2
Operating Labor	\$0	\$0
Admin and Support labor	\$0	\$0
Maintenance Material and Labor	\$18,000	\$39,000
Total Fixed O&M Costs	\$18,000	\$39,000
Variable Costs		
Lime Reagent	\$108,000	\$286,000
Byproduct Disposal	\$2,000	\$19,000
Auxiliary Power	\$197,000	\$320,000
Total Variable O&M Costs	\$307,000	\$625,000
Total Annual O&M Costs	\$325,000	\$664,000
Net Annual O&M Cost (\$/MWh)	0.18	0.20

O&M Cost represent costs above the baseline (existing system)

3.5.1.5 Annualized Total Cost

In order to effectively compare the cost of installing, operating, and maintaining the SO₂ control systems, capital and O&M costs should be evaluated on an annualized basis. The Annualized Total Cost (ATC) for SO₂ control systems was calculated based on overnight construction period (2019), followed by a 20-year service life. O&M costs were based on first year (2019) cost. No salvage value was assumed at the end of the service life for any of the control technology alternatives. The results are presented in Table 3-8 and Table 3-9 for Unit 1 and Unit 2, respectively, along with the emissions reduction, resultant emissions rate and the Unit Control Cost. The Unit Control Cost is the ATC divided by the annual tons of additional SO₂ emissions that would be controlled by implementation of the respective alternative.

Table 3-8: MRYS Unit 1 SO₂ Control System Annualized Total Cost

SO₂ Control Alternative	Percent Removal	Emission Rate lb/10⁶ Btu	Annual Emission (tpy)¹	Annual Emission Reduction (tpy)¹	Installed Capital Cost (\$)²	Annual O&M Cost (\$)	Annualized Total Cost (\$)³	Actual Unit Control Cost (\$/ton)⁴
Modified Wet FGD	97.4%	0.061	632	145	800,000	300,000	400,000	2,800
Baseline	96.8%	0.075	777	Baseline				

1. Based on baseline heat input of 20,726,417 MMBtu/yr

2. All Costs in 2019 dollars.

3. For ATC calculation, Capital Recovery Factor = 0.08368 and first year O&M Cost.

4. Overall control cost is ATC divided by actual annual emissions reduction of each alternative.

Table 3-9: MRYS Unit 2 SO₂ Control System Annualized Total Cost

SO ₂ Control Alternative	Percent Removal	Emission Rate lb/10 ⁶ Btu	Annual Emission (tpy) ¹	Annual Emission Reduction (tpy) ¹	Installed Capital Cost (\$) ²	Annual O&M Cost (\$) ²	Annualized Total Cost (\$) ³	Actual Unit Control Cost (\$/ton) ⁴	Incremental Unit Control Cost (\$/ton)
New Wet FGD	98.0%	0.050	859	1,305	142,500,000	4,300,000	16,200,000	12,400	128,000
Modified Wet FGD	97.7%	0.057	979	1,185	1,700,000	700,000	800,000	700	
Baseline	94.9%	0.126	2,164	Baseline					

1. Based on baseline heat input of 34,354,956 MMBtu/yr

2. All Costs in 2019 dollars.

3. For ATC calculation, Capital Recovery Factor = 0.08368 and first year O&M Cost.

4. Overall control cost is ATC divided by actual annual emissions reduction of each alternative.

The annual tons of SO₂ reduction in this RHCT analysis are calculated as the difference between the baseline emission rate and the controlled emissions and are assumed to be at the same heat input and unit operating time.

3.5.1.6 Cost Estimate Conclusion

In the RHCT guidelines, EPA does not provide definition, or even discussion of what Unit Control Costs are considered reasonable or unreasonable. NDDEQ has indicated that costs below \$4,500 per ton may be considered to be reasonable.

The Actual Unit Control Cost are used to evaluate the technology alternatives on a cost effectiveness basis. As can be seen from a review of Table 3-9, the cost of the new Unit 2 wet FGD alternative is excessively high with an actual and incremental control cost far greater than \$4,500 dollars per ton.

As can be seen from a review of Table 3-8 and Table 3-9, the wet FGD modification alternatives for both units are considered reasonable, with an Actual Unit Control Cost of \$2,800 and \$700 per ton for Unit 1 and Unit 2, respectively.

3.5.2 Energy Impacts

The energy impacts of replacing the existing Unit 2 wet FGD with a new wet FGD, or of upgrades to the existing wet FGD in the case of Unit 1, in terms of auxiliary power requirements, are given in Table 3-10 and Table 3-11. The primary energy impacts of the wet FGD alternative consists of the additional electrical load resulting from pumps and reagent preparation. Building HVAC and interior and exterior lighting loads are considered minimal.

Table 3-10: Auxiliary Energy Requirement of MRYS Unit 1 FGD Upgrades

RHCT Alternative	Energy Demand (kW)	Percent of Nominal Generation
Existing Wet FGD	5,170	2.2%
Upgraded Wet FGD	5,756	2.5%

Table 3-11: Auxiliary Energy Requirement of MRYS Unit 2 New FGD

RHCT Alternative	Energy Demand (kW)	Percent of Nominal Generation
Existing Wet FGD	9,658	2.2%
Upgraded Wet FGD	10,623	2.4%
New Wet FGD	11,853	2.7%

3.5.3 Non-Air Quality Environmental Impacts

Non-air quality environmental impacts of replacing the existing wet FGD with a new wet FGD or retrofitting the existing FGD systems are expected to be very similar to the impacts of the existing system. These may include hazardous waste generation, solid and aqueous waste streams. The primary change anticipated due to the use of a new wet FGD or modifying the existing FGD systems will be an incremental increase in the solids disposal rate as additional removal of SO₂ will result in increased byproduct.

While the economic evaluation of a new wet FGD system assumes overnight installation, the actual process to bid, design, purchase, and install a retrofitted new wet FGD system can take five years to implement. The actual process to bid, design, purchase, and install retrofits to an existing wet FGD system can take two to three years to implement.

3.5.4 SO₂ Control Technology Evaluation Conclusion

The energy impacts of a new wet FGD system are only incrementally higher than the existing system and are primarily driven by the increase in SO₂ removal. These incremental increases are acceptable.

The time period to install a new wet FGD system is significantly longer than the second ranked option (modifying the existing wet FGD) and would result in years of higher emission rates to achieve only a marginal increased removal rate. This would result in years of higher emissions before the RHCT would be installed.

Considering the existing systems are being replaced with like systems, there could be years of implementation delay with a new system for marginal removal improvement, and the high dollars per ton control cost includes low capital cost assumptions. This evaluation rejects the top ranked control technology for Unit 2 (new wet FGD) as RHCT.

While this is not used as the reason for the rejection of this top ranked option, comparison to the second ranked option (an upgrade to the existing wet FGD) indicates that the high annualized cost differential and low differential removal rate of the new FGD option result in an excessive incremental dollars per ton removed greater than \$128,000 per ton.

The time period to modify the existing wet FGD systems is significantly shorter than installing other new systems and would result in lower emission rates sooner than other options. The average control cost to modify the existing wet FGD systems is well below \$4,500 per ton. This evaluation results in the determination that modification of the Unit 1 and 2 wet FGD systems is RHCT.

This evaluation determined that 97.4% removal for Unit 1 and 97.7% removal on Unit 2 resulting in annual emission rates of 0.061 lb SO₂/MMBtu and 0.057 lb SO₂/MMBtu, respectively, should be modeled by WRAP as appropriate emission rates for the Step 5 review. The emission rates in this report are for WRAP modeling and are not proposed permit emission limits. As EPA has indicated, the Regional Haze Roadmap may be updated, and the results of the WRAP modeling will provide new information to be considered. Minnkota reserves the right to modify the four factor analysis once the Regional Haze Roadmap, any additional guidance and the results of the WRAP modeling are available. In addition, Minnkota reserves the right to conduct a 5th factor analysis based on visibility modeling once the results of the WRAP modeling are available.

This analysis is provided to assist the NDDEQ in the WRAP modeling and is not intended to serve as an agreement by Minnkota to any changes in permitted emission limits or permit conditions.

4.0 REGIONAL HAZE CONTROL TECHNOLOGY RESULTS

This report presents the analysis of control technologies for nitrogen oxides (NO_x), and sulfur dioxide (SO₂) for Minnkota Power Cooperative Inc.'s Milton R. Young Station (MRYS) Units 1 and 2. The final result of this analysis is a Regional Haze Control Technology (RHCT) for each unit based upon "the costs of compliance, the energy and non-air quality environmental impacts of compliance, any pollution control equipment in use at the source, the remaining useful life of the source..." (70 FR 39163). The presented emission rates in this section are the RHCT recommended rates for evaluation in Step 5 of a RHCT evaluation.

The first four steps of RHCT are used to identify technologies, determine feasibility and evaluate cost, energy, non-air quality and useful life impacts. This analysis reviewed technologies on these factors starting from the baseline of the existing units that include ASOFA/SNCR for NO_x control and wet FGDs for SO₂ control. The RHCT analysis does not review technologies that do not achieve at least the baseline level of performance.

As stated in previous sections of the report, the first four steps of the technology evaluation provided for in the Guidelines were completed for both Units. Each pollutant required a different approach in order to determine RHCT emission rate. This section provides a brief description of the approach used for each pollutant and summarizes the results.

For NO_x emissions, the top ranked technically feasible control technology for both units is the use of RRI in combination with SNCR and ASOFA. However, the RRI+SNCR system is not an economically effective NO_x control alternative for either Unit 1 or Unit 2 with control cost of \$11,100 and \$5,900 per ton of NO_x removed, respectively.

The Unit Control Costs for the next top ranked control technology, optimized SNCR system, is above \$4,500 per ton on Unit 1 (\$96,500 per ton) and Unit 2 (\$7,500 per ton). From an economic analysis viewpoint, optimized SNCR systems are not economically effective NO_x controls for either unit.

This evaluation concludes that the existing SNCR/ASOFA systems on both units are the top ranked control technologies.

For SO₂ emissions, the top ranked technology for Unit 2 was to replace the existing wet scrubber with a new wet scrubber. This technology was evaluated and rejected primarily because it was determined to be excessively costly on a dollars per ton removed basis (\$12,400 per ton). Furthermore, this top ranked control technology provided only limited additional removal for an order of magnitude additional costs compared to the second ranked control technology and will take years longer to implement than the second ranked technology.

The next highest ranked control technology (and also top ranked for Unit 1) is to retrofit the existing wet FGDs to increase removal. The OEM of the Unit 1 scrubber was engaged to evaluate how to increase the Unit 1 scrubber removal and re-evaluate a previous study they performed to increase removal in the Unit 2 scrubber. The mechanical upgrades the OEM included are replacing pump motors and changing nozzle designs. The various changes to operating conditions were evaluated based on the plant's previous operating history and experience to consider which conditions will improve removal, while working with the existing system and not impacting removal or reliability. There are no sufficient economic or energy reasons to reject modifying the existing scrubbers. There are non-environmental impacts to consider associated with scrubber operational changes due to potential scaling in the absorber and the long-term impact to the scrubber ponds. However, these impacts are considered manageable based on the operational changes to stoichiometric ratio and total suspended solids included in this evaluation. Based upon this analysis, modifying the existing wet FGDs in both Units is the top ranked RHCT option for SO₂ emissions.

Table 4-1 and Table 4-2 summarize the control technologies and associated emission rates recommended for Step 5 evaluation for each pollutant and for each unit. The RHCT emission rates are presented as annual averages based on the economic evaluation.

Table 4-1: RHCT Step 5 Annual Average Emission Rate, MRYS Unit 1

Pollutant	Control Technology	Emission Rate (lb/million Btu)
NO _x	Existing Selective Non-Catalytic Reduction and Advanced Separated Over Fire Air	0.332
SO ₂	Modify the existing Wet Flue Gas Desulfurization system	0.061

Table 4-2: RHCT Step 5 Annual Average Emission Rate, MRYS Unit 2

Pollutant	Control Technology	Emission Rate (lb/million Btu)
NO _x	Existing Selective Non-Catalytic Reduction and Advanced Separated Over Fire Air	0.334
SO ₂	Modify the existing Wet Flue Gas Desulfurization system	0.057

The four factor analysis was completed based on a request by the NDDEQ while utilizing the EPA 2016 RHR Guidance document. The NDDEQ has requested this information for the purpose of WRAP modeling. The emission rates in this report are for WRAP modeling and are not proposed permit emission limits. As EPA has indicated, the Regional Haze Roadmap may be updated, and the results of the WRAP modeling will provide new information to be considered. Minnkota reserves the right to modify the four factor analysis once the Regional Haze Roadmap, any additional guidance and the results of the WRAP modeling are available. In addition, Minnkota reserves the right to conduct a 5th factor analysis based on visibility modeling once the results of the WRAP modeling are available.

This analysis is provided to assist the NDDEQ in the WRAP modeling and is not intended to serve as an agreement by Minnkota to any changes in permitted emission limits or permit conditions.

Center, ND 58530-9507

Re: Fours Factors Analysis
M.R. Young Station

Dear Mr. Thomas:

The Department has conducted an initial review of the Four Factors Analysis that was submitted for the M.R. Young Station. Based on that review, we have the following comments:

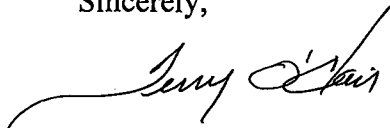

1. All estimates of costs should be based on current (2019) dollars not 2021 dollars. EPA's Control Cost Manual, Section 1, Chapter 2, states "The method for estimating TCI in this Manual is an "overnight" estimation method. This method estimates capital cost as if no interest was incurred during construction and therefore estimates capital cost as if the project is completed "overnight." An alternate way of describing this method is the present value cost that would have to be paid as a lump sum up front to completely pay for a construction project." All estimates of capital cost must be consistent with the Control Cost Manual.
2. Section 1.1.5 and the various tables indicate the baseline emission rates were based on the maximum 30-day rolling average from 2014-2018. Baseline emissions should represent expected future **annual emissions**. Use of the maximum 30-day rolling average will generally overpredict baseline emissions. Annual average emission rates would be a better representation if operating conditions are expected to remain the same. Based on past annual emissions at M.R. Young Station, we do not disagree with the stated baseline emissions at this time (see comment 6); however, we disagree with the methodology.
3. The cost of Rich Reagent Injection (RRI) appears to be excessive. EPA's revised Control Cost Manual estimates the capital cost of RRI at \$8-12/kw for a 500 MW plant. The Unit 2 capital cost estimate for RRI+SNCR/ASOFA was \$15,828,000 with \$2,774,000 for optimized SNCR/ASOFA. It appears that the cost of RRI equates to \$27.47/kw $((\$15,828,000 - \$2,744,000) / 477,000 \text{ kw})$, more than double EPA's estimate (Unit 1 calculated at \$30.16/kw). The capital cost estimated for M.R. Young Unit 2 is also more than double the estimated capital cost for RRI at Leland Olds Unit 2 (\$12.44/kw) and the

Coyote Station (\$13.43/kw) which are similar size units. Please revise the estimates for both units or provide a detailed explanation for the high cost.

4. Many cost estimates throughout the analysis are based on vendor budgetary quotes or engineering estimates. When cost estimates are not based on the EPA's Control Cost Manual, evidence for the estimate must be provided. In other words, if vendor quotes or engineering estimates are used for calculations, evidence of those quotes or estimates must be provided in the analysis.
5. Sections 2.5.1.5 and 4.4.1.5 discuss "levelizing" of capital and O&M costs. As discussed in the Round 1 SIP Approval/FIP, "levelizing" of costs using the normal electric utility industry method is not acceptable (see 77 FR 201916 – 201917). Levelizing the "Installed Capital Cost" is not allowed. The cost estimates must be revised to be consistent with the Control Cost Manual.
6. In Tables 3-8 and 3-9, footnote 5 indicates the projected emissions (tpy) for a "Modified Wet FGD" were based on future higher sulfur coal. It appears the baseline emission rates were also based on future higher sulfur coal. If so, footnote 5 should also be placed on the "Baseline" in column 1 and coal sampling data provided to justify the rate. If not, the high baseline emission rates should be explained.

We ask that you revise the analysis and resubmit it as soon as possible. If you have any questions, please contact Tom Bachman of my staff at (701) 328-5188.

Sincerely,

Terry L. O'Clair, P.E.
Director
Division of Air Quality

FILEMs. Abbie Krebsbach
Montana Dakota Utilities
400 N Fourth Street
Bismarck, ND 58501Re: Regional Haze
Second Planning Period

Dear Ms. Krebsbach:

The Department of Health (Department) has begun work on the second planning period (Round 2) State Implementation Plan (SIP) for regional haze. In Round 1 of the regional planning process, the emphasis was on Best Available Retrofit Technology (BART) and making reasonable progress towards the national visibility goal. In Round 2, there are no BART requirements; therefore, we will focus on making reasonable progress. The reasonable progress analysis will be made using the four factors in Section 169A(g)(1) of the Clean Air Act:

The four factors are:

1. The cost of compliance
2. The time necessary to achieve compliance
3. The energy and non-air quality environmental impact of compliance; and
4. The remaining useful life of any existing source subject to such requirements

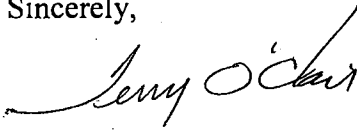

Guidance provided by the U.S. Environmental Protection Agency (Draft Guidance on Progress Tracking Metrics, Long Term Strategies, Reasonable Progress Goals and Other Requirements for Regional Haze State Implementation Plans for the Second Implementation Period at https://www.epa.gov/sites/production/files/2016-07/documents/draft_regional_haze_guidance_july_2016.pdf) indicates the Department must address 80% of the visibility impairment caused by in-state sources. Data from the IMPROVE monitoring sites at Theodore Roosevelt National Park (TRNP) and Lostwood Wilderness Area (LWA) indicate that sulfates and nitrates continue to be the largest contributors to visibility impairment in these areas. The primary precursors of sulfates and nitrates are emissions of sulfur dioxide (SO₂) and nitrogen oxides (NO_x).

Coal-fired electrical generating units have been identified as one of the largest source of sulfur dioxide and nitrogen oxides in North Dakota. Therefore, the Department requests that you prepare a "four factors" analysis for your coal-fired electrical generating units. The analysis should be prepared using the draft EPA guidance noted above. The Department will identify other sources in North Dakota that will be required to submit a four factors analysis.

The Department will be working with the Western Regional Air Partnership (WRAP) to prepare the Round 2 SIP. WRAP will be conducting air quality modeling of regional emissions reductions in early 2019. The Department asks that your "four factors" analysis be submitted by January 31, 2019.

If you have any questions, please contact David Stroh of my staff at (701)328-5188.

Sincerely,

Terry L. O'Clair
Director
Division of Air Quality

Re: Regional Haze Round 2 "Four-Factor" Analysis Report for SO₂ and NO_x Emissions Control at
R.M. Heskett Station Unit 1 and Unit 2

Dear Mr. Stroh:

Enclosed is Montana-Dakota Utilities Co. (Montana-Dakota) Regional Haze Round 2 "Four-Factor" Analysis Report for SO₂ and NO_x Emissions Control at R.M. Heskett Station Unit 1 and Unit 2. This report contains the analysis the North Dakota Department of Health (NDDH) requested (for sulfur dioxide and nitrogen oxides) as applied to the review of emissions controls under the Regional Haze program for our coal-fired electrical generating units.

The NDDH May 2, 2018 letter requested that we prepare this report according to Draft Guidance provided by the U.S. Environmental Protection Agency (EPA). EPA has made known in the agency's September 11, 2018 Regional Haze Reform Roadmap that updated guidance, replacing the current Draft Guidance, as well as implementation tools, for this planning period will be available in future. However, the updated guidance has not yet been published. Montana-Dakota also understands other states in Region 8 have not yet requested a similar review process be completed by industry. Considering the information gained in the regional modeling process, future updated guidance from EPA, the short timeframe to complete and submit the attached report, and the potential need to consider site-specific conditions and costs, Montana-Dakota reserves the right to review and modify this analysis.

If you have any questions or would like to discuss the report conclusions, please contact me at (701) 222-7865.

Sincerely,

Mark Dihle
Sr. Environmental Scientist

1 Introduction

The Regional Haze (RH) Rule published on July 15, 2005 by the U.S. Environmental Protection Agency (EPA) defines regional haze as “visibility impairment that is caused by the emission of air pollutants from numerous sources located over a wide geographic area. Such sources include, but are not limited to, major and minor stationary sources, mobile sources, and area sources.” The RH rule requires states to submit a series of state implementation plans (SIPs) to protect visibility in certain national parks and wilderness areas, known as mandatory Federal Class I areas. The original State SIPs were due on December 17, 2007 and included milestones for establishing reasonable progress towards the visibility improvement goals, with the ultimate goal to achieve natural background visibility by 2064. The original SIP was informed by best available retrofit technology (BART) analyses that were completed on all subject-to-BART sources. The second planning period (Round 2) requires development and submittal of updated state SIPs by July 31, 2021.

The North Dakota Department of Health (NDDH) has requested Montana-Dakota Utilities Co. (MONTANA-DAKOTA) R.M. Heskett Station (Heskett Station) complete a four-factor analysis, as outlined in Section 169A(g)(1) of the Clean Air Act (CAA) as part of RH Round 2. Per the May 2, 2018 letter from the NDDH and separate confirmation from NDDH, the four-factor analysis is only required for direct emissions of sulfur dioxide (SO₂) and nitrogen oxides (NO_x). The reasonable progress analysis is made using the following four factors:

1. The cost of compliance;
2. The time necessary to achieve compliance;
3. The energy and non-air quality environmental impact of compliance; and
4. The remaining useful life of any existing source subject to such requirements.

This report describes the background and methods for conducting a four-factor analysis for sulfur dioxide (SO₂) and nitrogen oxides (NO_x) as applied to the review of emissions controls under the RH program at Heskett Station located two miles north of Mandan, ND. Heskett Station operates two coal fired electric generating units. Commercial operation commenced on Heskett Station Unit 1 (25 megawatt) in 1954 and Heskett Station Unit 2 (75 megawatt) in 1963. In 1987, Unit 2 was converted from a Riley Stoker Spreader boiler to an atmospheric fluidized-bed combustor (discussed below in Section 1.1.1.2).

The primary precursors of sulfates and nitrates are emissions of sulfur dioxide (SO₂) and nitrogen oxides (NO_x). Guidance provided by the U.S. Environmental Protection Agency (EPA) indicates the Department must address 80% of the visibility impairment caused by in-state sources. Data from the IMPROVE monitoring sites at Theodore Roosevelt National Park (TRNP) and Lostwood Wilderness Area (LWA) indicate that sulfates and nitrates continue to be the largest contributors to visibility impairment in these areas.

MONTANA-DAKOTA understands that NDDH is requesting the four-factor analysis and subsequent emissions performance numbers for submittal to the Western Regional Air Partnership (WRAP) for modeling of visibility impacts at Class I areas (i.e., TRNP and LWA).

MONTANA-DAKOTA also understands, to-date, no other states have yet requested a similar review process be completed by industry. Considering that no other WRAP industry partners are providing information, the short timeframe to complete this work, and the September 11, 2018 Regional Haze Reform Roadmap (roadmap) from EPA indicating impending implementation tools and updated guidance for the second planning period is not yet available, MONTANA-DAKOTA reserves the right to review and modify the assumptions used in this analysis, primarily concerning site-specific conditions for cost (including capital costs and actual emissions reductions potential/performance) and remaining useful life of the affected sources.

1.1 Background, Historical and Current Emissions Summary and Future Operational Considerations

MONTANA-DAKOTA Heskett Station was not subject to a formal BART review as part of Round 1 of RH. Unit 1 was not considered a BART-eligible source due to an operation commencement date before 1962 and NDDH determined it was further exempted from detailed analysis based on a calculated Q/D (emission rate (Q) divided by the distance (D) to the nearest Class I area) of less than 10. Unit 1 does not operate with any add-on SO₂ or NO_x controls currently. While Unit 2 was originally considered a BART-eligible source, it was ultimately exempted from formal BART requirements due to modeling that demonstrates a contribution of less than 0.5 deciviews of visibility degradation in any Class I area. However, MONTANA-DAKOTA initiated a draft BART evaluation on Unit 2 in early 2006 with excerpts of that draft submitted to NDDH, as documented in Supplement No. 1 to the North Dakota State Implementation Plan (SIP) for RH. R.M. Heskett Station was reviewed for controls under the reasonable progress goals of North Dakota's RH SIP. Under that portion of the SIP, the NDDH included a federally enforceable permit requiring Heskett Station to comply with an SO₂ emissions rate of 0.60 lb/mmBtu, which is equal to a 70% reduction of SO₂ emissions (coal-to-stack)¹. Heskett Station accomplished this in 2017 by implementing a project that replacing a portion of the sand utilized in the Unit 2 boiler fluidized bed with limestone. In 2017, the limestone addition project was completed. Unit 2 does not operate with add-on NO_x controls currently, although the lower temperatures of the AFBC provides some NO_x combustion control benefit. Both Units currently cycle load as called upon for generation needs (Unit 1 typically down to 9 MW; Unit 2 typically down to 56 MW), and these decreased operating levels result in less overall air pollution.

EPA's draft guidance allows states to use a screening step to select sources or groups of sources for which a four-factor analysis shall be completed. While the current draft guidance does not provide clear definition on conducting that screening step, the September 2018 roadmap explicitly states that the areas

¹ R.M. Heskett Station Air Pollution Control Title V Permit to Operate, T5-F76001.

of focus in the updated guidance will include “providing states with additional information and context regarding screening sources before in-depth analysis”.

As a reference point, MONTANA-DAKOTA has calculated a preliminary Q/D Analysis for both Unit 1 and Unit 2. For Unit 1, the preliminary Q/D is determined using the average of the annual tons of NO_x and SO₂ (combined) emitted from 2012 to 2017, as reported to NDDH through the Annual Emissions Inventory Report (AEIR), and the distance to the nearest class 1 area consistent with the ND RH SIP (182 kilometers). For Unit 2, the preliminary Q/D is determined using the annual tons of NO_x and SO₂ (combined) emitted in 2017, as reported to NDDH, and the distance to the nearest Class I area consistent with the ND RH SIP. 2017 was assumed representative of current of and future emissions due to implementation of limestone injection at Unit 2 in 2017. Preliminary Q/D values are shown below:

Table 1-1 Preliminary Q/D for Heskett Station

Unit	SO ₂ + NO _x (tons)	Distance (km)	Q/D (tons/km)
Unit 1	1,194	182	6.6
Unit 2	2,899	182	13.5
Combined Source	4,094	182	18.0

MONTANA-DAKOTA notes that the combined source emissions are less than the individual Unit 2 source Q/D from the ND RH SIP for Round 1. Considering the lower emissions trend for both units, it is expected that visibility modeling for Heskett Station would demonstrate commensurately lower visibility impairment. MONTANA-DAKOTA reserves the right to review and modify the assumptions used in this analysis.

1.1.1 Emissions Summary

1.1.1.1 Heskett Station Unit 1

Heskett Station Unit 1 is a 25 MW, lignite fired, spreader stoker boiler rated at 387.63 MMBtu/hour. The boiler is capable of burning up to approximately 30 tons of coal per hour. Unit 1 also has the capability to blend (with lignite) and combust tire derived fuel (TDF), and does so as a method to comply with the Mercury and Air Toxics Standard (MATS) mercury (Hg) emissions limit for units designed to burn low-rank virgin coal. As permitted, TDF can account for up to 4 tons/hr of the fuel combusted on a calendar quarter average, but the actual amount combusted is much less. Unit 1 was constructed in 1954 and an Electrostatic Precipitator (ESP) was later installed to control particulate emissions. Unit 1 currently utilizes over-fire air techniques to assist with NO_x emissions mitigation. As is common with older units, there is limited ductwork and space between the boiler and the stack for any emissions control additions.

Unit 1 NO_x Emissions Summary

Heskett Station Unit 1 is estimated to have the potential to emit 762 tons of NO_x annually, if operated 100% of the year. Potential NO_x emissions are calculated using AP-42, Vol. I, Chapter 1.7 for lignite combustion emissions factor of 5.8 lb NO_x/ton of coal combusted and assuming firing at the combustion capability of the unit (30 tons per hour) for a full year. There is no continuous emissions monitoring

system (CEMS) for NO_x at station 1. However, based on the actual amount of coal combustion, since 2012, annual NO_x emissions reported at Heskett Station Unit 1 total less than half of what the unit can potentially emit. The lower annual emissions are due to operating at a rate lower than maximum capacity. Actual emissions reported since 2012 are shown in Figure 1 below. Section 1.1.2 of this report discusses the operating capacity at Heskett Station.

Figure 1 Heskett Station Unit 1 Total Annual NO_x Emissions

Unit 1 SO₂ Emissions Summary

Heskett Station Unit 1 actual SO₂ emissions from 2012 through 2017 are shown below in Figure 2. The figure demonstrates that, since 2012, Unit 1 actual SO₂ performance on a lb/MMBtu basis has been much less than the permitted limit of 3.0 lb/MMBtu (3-hour rolling average). The data points shown on the graph are presented as monthly averages and are not to be construed as a compliance demonstration against the 3-hour rolling average permitted limit. Unit 1 actual mass emissions are determined as measured from the unit's CEMS. Emissions data are shown as a lb/MMBtu on a monthly average basis and includes all periods of operation.

Figure 2 Heskett Station Unit 1 Average Monthly SO₂ Emissions

1.1.1.2 Heskett Station Unit 2

Heskett Station Unit 2 is a 75 MW, lignite-fired, atmospheric fluidized-bed combustor (AFBC) rated at 916.5 MMBtu/hour. The boiler is capable of firing up to approximately 75 tons of coal per hour. In atmospheric fluidized bed combustion, coal is burned in a hot sand (and limestone) bed that is aerated from bubble caps underneath. Unit 2 also has the capability to combust TDF. Unit 2 was constructed in 1963 as a Riley Stoker Spreader boiler, was converted to an AFBC in 1987 and later installed an ESP to control particulate matter emissions. Unit 2 also has limited ductwork and space between the boiler and the stack.

The conversion of the original boiler was to an AFBC, which is different from a circulating fluidized bed boiler design. The Unit 2 AFBC media is maintained in the bottom of the boiler at approximately 4 feet or less in height and has boiler tubes immersed within the bed. Transfer of heat to the tubes in the bed is optimal with certain blends of sand, limestone, and ash. Feed rate of new material to the bed and drainage of spent material can be adjusted for system management. An AFBC is also different from circulating fluidized bed boilers where the bed media circulates higher in the boiler with the flue gas; any carryover media is captured, separated from the flue gas, and returned to the boiler. An AFBC has minimal sand media carryover since the bed height is relatively low.

Unit 2 NO_x Emissions Summary

Heskett Station Unit 2 actual NO_x emissions from 2012 through 2017 are shown below in Figure 3. The figure demonstrates that, since 2012, Unit 2 actual NO_x performance on a lb/MMBtu monthly average basis has been less than the permitted limit of 0.46 lb/MMBtu (12-month rolling average). The permitted limit is incorporated into the below figure as a reference point for comparison to current actual emissions. The data points shown on the graph are presented as monthly averages and are not to be construed as a

compliance demonstration against the 12-month rolling average permitted limit. Unit 2 actual mass emissions are determined as measured from the unit's CEMS. Emissions performance data is shown as a lb/MMBtu on a monthly average basis and includes all periods of operation.

Figure 3 Heskett Station Unit 2 Average Monthly NOx Emissions

Unit 2 SO₂ Emissions Summary

Heskett Station Unit 2 actual SO₂ emissions from 2012 through 2017 are shown below in Figure 4. Heskett Station implemented a limestone addition to the sand bed for Unit 2 for RH emission reductions in 2017. An SO₂ limit of 0.60 lb/MMBtu was applied to Unit 2 and Heskett Station has demonstrated compliance with this 12-month rolling average limit. The permitted limits are incorporated into the below figure as a reference point for comparison to current actual emissions. The data points shown on the graph are presented as monthly averages and are not to be construed as a compliance demonstration against the rolling average permitted limits. Emissions performance data is shown as a lb/MMBtu on a monthly average basis and includes all periods of operation. Since implementation of the limestone injection project, actual SO₂ emissions have decreased from approximately 165 lb/hr to 110 lb/hr on a monthly average basis.

Figure 4 Heskett Station Unit 2 Average Monthly SO₂ Emissions

1.1.2 Operating Capacity

Since the early 2000's, baseload operations at coal-fired power plants located across the Western United States has decreased significantly in annual utilization. Since 2011, the majority of coal fired electric generating units (EGU) have spent less than 30% of their operating days in baseload operating mode.² Heskett Station is no exception to that trend. Since 2012, the annual capacity factors (on a lb/MMBtu basis) are as follows:

Table 1-2 Annual Capacity Factor at MONTANA-DAKOTA Heskett Station Unit 1 and Unit 2

Year	Annual Capacity Factor (lb/MMBtu basis)	
	Unit 1	Unit 2
2012	43%	60%
2013	50%	52%
2014	46%	69%
2015	44%	66%
2016	31%	65%
2017	27%	65%
2018 (through October 2018)	37%	65%
Average	40%	63%

The average capacity factors (on a lb/MMBtu basis) since 2012 are 40% for Unit 1 and 63% for Unit 2. MONTANA-DAKOTA does not anticipate a change in the trend of decreasing firing moving into the future

² Western Interstate Energy Board (2018). "The Role of Coal in the West" [PowerPoint slides]. Retrieved from <http://www.wrapair2.org/pdf/The%20Role%20of%20Coal%20in%20the%20West-Presentation.pdf>

and, therefore, is appropriately utilizing a baseline emissions estimate for both NO_x and SO₂ according to the average operating capacity factor (utilization rate) and the existing emissions limits for Unit 1 and Unit 2. The current EPA draft guidance states that baseline emissions can be determined according to past practice.³ MONTANA-DAKOTA reserves the right to change (or update) the operating capacity factors in future rounds of RH review, as warranted. Figure 5 and Figure 6 show the annual tons of NO_x and SO₂ emitted from Unit 1 and Unit 2, respectively since 2012.

Figure 5 Heskett Station Unit 1 Total Annual NO_x and SO₂ Emissions

The declining annual actual emissions for Unit 1 are not specifically a result of additional pollution control equipment additions, but more a result of declining unit utilization year-over-year from 2013 through 2017, as listed in Table 1-2.

Figure 6 Heskett Station Unit 2 Total Annual NO_x and SO₂ Emissions

Unit 2 has operated at a fairly consistent, but reduced, capacity since 2012, which is confirmed by the total annual NO_x emissions from 2012 through 2017. The reduction in annual SO₂ emissions starting in 2016 at Unit 2 is a result of the initial operation and testing of the limestone injection project that was fully implemented in early 2017.

³ EPA July 2016 Draft Guidance, Section 6.2 (pg. 59): "In projecting future baseline emissions, typical past actual emission rates may be assumed even if lower than permitted emission rates, assuming there is no evident basis for assuming a change in emission rates"

1.2 Four-Factor Analysis Approach

The four-factor analysis is completed following the approach summarized below, as outlined in EPA's July 2016 draft guidance.

1.2.1 Identify all Emissions Control Options

Prior to completing the required four-factor analysis, all potentially available and technically feasible emissions control options for review are identified. Potentially available emissions control options include both add-on control equipment and process improvement applications. To be considered available and technically feasible, a control must have been previously installed and operated successfully on a similar source under similar physical and operating conditions. Novel controls that have not been demonstrated on full-scale, coal-fired utilities are not considered as part of this analysis. Instead, this evaluation focuses on commercially demonstrated control options.

All control options identified as available and technically feasible are then evaluated against the "four factors". Under this analysis, NO_x and SO₂ emissions control options are evaluated for each unit individually.

1.2.2 Factor #1 – The Cost of Compliance

As part of Factor #1, the capital and annual operating and maintenance (O&M) costs of a control measure are estimated. As directed by the draft guidance, for purposes of Round 2, costs of emissions controls follow the accounting principles and generic factors from the EPA Air Pollution Control Cost Manual (Control Cost Manual) unless site specific factors are available and required to develop an accurate and representative control costs estimate. Under this step, the costs of compliance (dollar per ton basis) will be compared to the costs that other similar sources have had to bear in other regulatory actions to determine whether a control measure is reasonable.

The cost of compliance is calculated on a \$/ton basis following the Control Cost Manual site-specific information is referenced and utilized when appropriate. However, if key information is unavailable, and should further cost refinement be necessary, a study would be required. This would mandate additional time and cost to determine the impact due to constraints of the current system, such as an extended need for shutdown, rerouting of piping to allow necessary residence time, potential redesign of backend heat recovery and associated costs that have not been evaluated. MONTANA-DAKOTA reserves the right to amend all items related to cost in the future.

The cost of compliance are categorized into capital and annual costs. Capital costs generally refer to the money required to design and build the system, and this includes direct costs, such as equipment purchases, and installation costs, such as foundations and installation of mechanical equipment. Indirect costs, such as engineering and construction field expenses, are also considered. Also taken into account when completing the economic feasibility (cost effectiveness) analysis are the baseline emissions (calculated as described above) and expected performance of the control device.

At the direction of the NDDH, this analysis uses an interest rate of 5.25% for the Round 2 four-factor economic analysis when determining annualized costs, MONTANA-DAKOTA reserves the right to use the default 7% (or another appropriate percentage) interest rate in future iterations of the economic analysis for RH Round 2 purposes. The Control Cost Manual states that "EPA policy specifies 7% interest for BACT review cost calculations". NDDH is following the EPA guidance from December 18, 2018⁴ email in which EPA suggests using the bank prime rate in method outline in Section 2.5.2 of the Control Cost Manual. However, the December 18, 2021 email also notes that the recommended rate can vary. This variability has recently been demonstrated by an increase to raise the rate quoted in the email from 5.25% to 5.5%. MONTANA-DAKOTA is an investor-owned utility and finances projects differently than other utilities that are able to participate in Rural Utility Service (RUS) Electric Loan Program financing.

The emissions reduction or degree of control for each evaluated technology that is used to determine the cost of compliance is expressed as a 12-month average basis and represents the annual tons of pollutant removed to account for expected variability in emissions and provide a comparable basis for each of the control options. Baseline emissions are determined relying on permitted emissions limits and actual/expected unit operation.

1.2.3 Factor #2 – Time Necessary for Compliance

Under Factor #2, the time necessary for a source to implement a control measure to achieve compliance with a proposed emissions limitation is given consideration by setting reasonable deadlines for selected control. This includes the planning and installation of new emissions controls.

1.2.4 Factor #3 – Energy and Non-Air Environmental Impacts

The energy and non-air environmental impacts of each control technology are evaluated under Factor #3.

The environmental impact analysis assesses collateral environmental impacts associated with control of the pollutant in question. Impacts considered may include solid or hazardous waste generation, wastewater discharges from a control device, increased water consumption, and land use. The environmental impact analysis is conducted based on consideration of site-specific circumstances.

The energy impact analysis considers whether use of an emissions control technology results in any significant or unusual energy penalties or benefits. Energy use may be evaluated on an energy used per unit of production basis; energy used per ton of pollutant controlled or total annual energy use. Energy impacts may consider whether use of an emissions control technology will have an adverse impact on local energy supplies due to increased fuel consumption or the loss of fuel production or power generation.

⁴ Wortstell, Aaron (EPA). "RE: Regional Haze Economic Analysis." Message to Tom Bachman. December 18, 2018. Email.

1.2.5 Factor #4 – Remaining Useful Life of the Source

The remaining useful life of a source is considered the difference between the date that controls will be put in place and the date the facility permanently ceases operation. The remaining useful life of the source is typically longer than the useful life of the emissions control measure unless there is an enforceable cease-operation requirement. However, under Factor #4, if the useful life of the source is less than the remaining useful life of the control measure through a federally or state enforceable requirement, then that can be taken into consideration when evaluating emissions reductions, amortized costs, and cost per ton.

The remaining useful life of the two coal-fired units (Heskett Station Unit 1 and Unit 2) continues to be reviewed through MONTANA-DAKOTA'S Integrated Resource Planning (IRP) process, as required by state utility regulatory commissions. This IRP analysis considers many factors including facility age, major maintenance needs, future environmental compliance costs, and economic competitiveness to other alternatives, to determine appropriate planning for retirement of units. Until the IRP is concluded, MONTANA-DAKOTA will assume a 20-year remaining useful life for purposes of this four-factor analysis. It is possible that retirement could occur earlier than the assumed 20 years considering the culmination of additional environmental regulatory requirements and economic competitiveness of these units.

2 Unit 1 Nitrogen Oxides (NOx) Four-Factor Analysis

There are three mechanisms by which NOx production occurs: thermal, fuel, and prompt NOx. Fuel bound NOx is a primary concern with solid and liquid fuel combustion sources; it is formed as nitrogen compounds in the fuel are oxidized in the combustion process. The secondary mechanism of NOx production is through thermal NOx formation. This mechanism arises from the thermal dissociation of nitrogen and oxygen molecules in combustion air. The thermal oxidation reaction is as follows:

Downstream of the flame, significant amounts of NO₂ can be formed when NO is mixed with air. The reaction is as follows:

Thermal oxidation is a function of the residence time, concentration of combustion gases (primarily nitrogen and oxygen) in the inlet air, and peak reaction temperature. Prompt NOx is a form of thermal NOx which is generated at the flame boundary. It is the result of reactions between nitrogen and carbon radicals generated during combustion. Only minor amounts of NOx are emitted as prompt NOx.

2.1 NOx Emissions Control Measures

There are several potentially available methods to control NOx emissions (see Table 2-1); however, not all are applicable for implementation at Unit 1. Accordingly, as part of this four-factor analysis, MONTANA-DAKOTA has narrowed the list of NOx control technology options for review to those that are functionally applicable for a retrofit installation at the Heskett Station Unit 1. The NOx retrofit control options are identified based on a review of available technical information.

Retrofit NOx control technologies can be divided into two general categories: (1) combustion controls, and (2) post-combustion controls. Combustion controls reduce the amount of NOx that is generated in the boiler, while post-combustion controls remove NOx from the boiler exhaust gas.

Table 2-1 List of Potentially Available Retrofit NOx Control Options

Control Technology
Combustion Controls
<ul style="list-style-type: none"> • Low NOx Burners • Overfire Air (OFA) • Flue Gas Recirculation (FGR) • Burner Tempering (Water Injection)
Post-Combustion Controls
<ul style="list-style-type: none"> • Selective Non-Catalytic Reduction (SNCR) • Selective Catalytic Reduction (SCR) <ul style="list-style-type: none"> ○ High-Dust SCR ○ Low-Dust SCR
Innovative Control Technologies
<ul style="list-style-type: none"> • Rotating Overfire Air (ROFA) • Boosted Overfire Air (BOFA) • ROFA + SNCR (Rotamix™) • NOxStar™ • Exxon Thermal DeNOx™ • Pahlman Process • Wet NOx Scrubbing LOTox™

2.1.1 Combustion Controls

The rate of NOx formation in the combustion zone is a function of free oxygen, peak flame temperature and residence time. Combustion techniques designed to minimize the formation of NOx will minimize one or more of these variables. Combustion control options considered for Heskett Station Unit 1 are summarized below.

2.1.1.1 Low NOx Burners (LNB)

LNB technology utilizes advanced burner design to reduce NOx formation through the restriction of oxygen, flame temperature, and/or residence time. LNB is a staged combustion process that is designed to split fuel combustion into two zones. In the primary zone, NOx formation is limited by either one of two methods. Under staged air rich (high fuel) condition, low oxygen levels limit flame temperatures resulting in less NOx formation. The primary zone is then followed by a secondary zone in which the incomplete combustion products formed in the primary zone act as reducing agents. Alternatively, under staged fuel lean (low fuel) conditions, excess air will reduce flame temperature to reduce NOx formation. In the secondary zone, combustion products formed in the primary zone act to lower the local oxygen concentration, resulting in a decrease in NOx formation.

LNB technology is not a technically feasible control option at a stoker fired traveling grate furnace, and therefore, will not be considered further for implementation at Unit 1.

2.1.1.2 Overfire Air (OFA)

Overfire air (OFA) diverts a portion of the total combustion air from the burners and injects it through separate air ports above the top level of burners. OFA is the typical NO_x control technology used in lignite-fired boilers and is primarily geared to thermal NO_x reductions. Staging of the combustion air creates an initial fuel-rich combustion zone for a cooler fuel-rich combustion zone. This reduces the production of thermal NO_x by lowering combustion temperature and limiting the availability of oxygen in the combustion zone where NO_x is most likely to be formed.

OFA technology is currently used to control NO_x emissions at Unit 1.

2.1.1.3 External Flue Gas Recirculation (FGR)

Flue gas recirculation is a flame-quenching technique that involves recirculating a portion of the flue gas from the economizer or air heater outlet and returning it to the furnace through the burner or windbox. The primary effect of FGR is to reduce the peak flame temperature through adsorption of the combustion heat by the relatively inert flue gas, and to reduce the oxygen concentration in the combustion zone. FGR reduces thermal NO_x generation in high-temperature emissions sources.

Additional ductwork and a blower would be required to recirculate flue gas. These elements must fit in the limited space around the burner. To integrate a blower and inject flue gas into the combustion zone of the existing unit would require a full design review and likely costly modifications to the existing combustion control scheme. Unit 1 currently utilizes OFA as a way to reduce thermal NO_x emissions; it is unlikely that FGR would result in any additional significant NO_x reductions. Further, FGR could result in reduced boiler capacity at an already small unit operating at reduced capacity.

For these reasons, FGR is not a technically feasible control option for implementation at Unit 1 and will not be considered further.

2.1.1.4 Burner Tempering (Water Injection)

The principle behind combustion tempering is to inject an atomized water spray into the high NO_x production zones of the furnace flame. The water spray reduces the temperature within the zone, resulting in lower NO_x production within the zone.

To integrate water injection into the combustion zone of the existing unit would require a full design review and likely costly modifications to the existing combustion control scheme. Burner tempering has been used on wall- and tangential-fired pulverized coal-fired units but not at a stoker fired traveling grate furnace and is therefore not a technically feasible control option for implementation at Unit 1. This technology is not considered further.

2.1.2 Post-Combustion Controls

NO_x can be reduced to molecular nitrogen (N₂) in add-on systems located downstream of the furnace area of the combustion process. The two main techniques in commercial service include the selective non-catalytic reduction (SNCR) process and the selective catalytic reduction (SCR) process. There are a number of different process systems in each of these categories of control techniques.

In addition to these treatment systems, there are a large number of other processes being developed and tested on the market. These approaches involve innovative techniques of chemically reducing, absorbing, or adsorbing NO_x downstream of the combustion chamber. One example of these alternatives is nonselective catalytic reduction (NSCR).

2.1.2.1 Selective Non-Catalytic Reduction (SNCR)

In the SNCR process, urea or ammonia-based chemicals are injected into the flue gas stream to convert NO to N₂ and water. SNCR control efficiency is typically 25% to 50%. Without the participation of a catalyst, the reaction requires a high temperature range to obtain activation energy. The relevant reactions are as follows:

At temperature ranges of 1470°F to 1830°F, reaction (1) dominates. At temperatures above 2000°F, reaction (2) will dominate. Flue gas temperature at the point of reagent injection can greatly affect removal efficiencies and the quantity of ammonia (NH₃) that will pass through unreacted (ammonia slip). At temperatures below the desired operating range, the NO_x reduction reactions diminish and unreacted NH₃ emissions increase. Above the desired temperature range, NH₃ is oxidized to NO_x resulting in low NO_x reduction efficiencies.

Mixing of the reactant and flue gas within the reaction zone is also an important factor to SNCR performance. The SNCR system must be designed to deliver the reagent in the proper temperature window, and allow sufficient residence time of the reagent and flue gas in that temperature window. In addition to temperature, mixing, and residence time, several other factors influence the performance of an SNCR system including reagent-to-NO_x ratio and NO_x concentration in the flue gas.

SNCR systems are capable of achieving a NO_x emissions reduction as high as 50 to 60 percent in optimum conditions (adequate reaction time, temperature, and reagent/flue gas mixing, high baseline NO_x conditions, multiple levels of injectors) with ammonia slips of 10 to 50 ppmvd. Typically, optimum conditions are difficult to achieve, resulting in emissions reduction levels of 20 to 40 percent. Potential performance is very site-specific and varies with fuel type, steam generator size, allowable ammonia slip, furnace carbon monoxide (CO) concentrations, and steam generator heat transfer characteristics.

The application of SNCR to Heskett Station Unit 1 has the potential to be technically feasible because furnace temperatures are assumed (note that there is not instrumentation currently in place to measure temperature) to be within the temperature window needed for NO_x reduction, and flue gas mixing and residence time within the boiler should promote the reaction kinetics. However, the effectiveness of an SNCR system at Heskett Station Unit 1 will be limited because of the design and boiler operating temperatures. The optimal condition locations are small due to the boiler size and type, and a boiler study would be required to more correctly predict feasibility and effectiveness at Unit 1. Even so, for purposes of this review, MONTANA-DAKOTA has assumed that SNCR could potentially be implemented at Unit 1 and has therefore included this in the four-factor analysis. Based on the calculated default control efficiency

from EPA, an SNCR could potentially provide a NO_x reduction of approximately 27% at Unit 1. With the uncertainty due to small boiler size and other issues, we reserve the right to refine this analysis in the future if necessary. MONTANA-DAKOTA is unaware of an SNCR system that is in operation today at a similar source utilizing an ESP for particulate matter control. A full review of the ESP's ability to accept and properly clean the flue gas would be needed to determine feasibility and possible costs.

2.1.2.2 Selective Catalytic Reduction (SCR)

Selective catalytic reduction (SCR) is a post combustion NO_x control technology in which NH₃ is injected into the flue gas stream in the presence of a catalyst. SCR control efficiency is typically 70% to 90%. NO_x is removed through the following chemical reaction:

The catalyst bed lowers the activation energy required for NO_x decomposition. The catalyst contains an active phase, such as vanadium pentoxide, on a carrier, such as titanium dioxide, and these are used for their ability to lower the activation energy required for NO_x decomposition. SCR requires an optimum temperature range of 650 to 800°F.

A "high-dust" SCR arrangement in which the reactor is located between the outlet of the economizer and the inlet of the air heater and upstream of particulate control is typically the preferred arrangement where technically feasible. These arrangements typically require soot blowers for catalyst cleaning. In a "low-dust" arrangement, the SCR reactor is located after the particulate control device. This arrangement is preferred when the fly ash contains a high level of contaminants that would block catalyst actions, and removing most of the fly ash from the flue gas will help prolong the catalyst life. Firing ND lignite coal that contains high amounts of organically bound inorganics (and has a higher total sodium content), results in a stream heavily laden with particulate matter and sodium that combine to plug (block) catalyst passages. Due to the likelihood of catalyst plugging and the ability of phosphorus, sodium, other alkali and alkaline earth cations organically bound in ND lignite to mask or blind a catalyst reactions if not already plugged, a high-dust SCR system is considered technically infeasible on both Units 1 and 2. A low-dust SCR (downstream of particulate control) would require reheat to bring the stream temperature back to the effective control range after it is cooled for particulate removal. There would still be important concerns with this arrangement due to the contaminants' unique properties to inhibit the catalyst from operating, but in theory the issues would be less than with a high-dust system.

Although it would appear to be a potentially a technically feasible control option, MONTANA-DAKOTA notes that installing SCR (even a low-dust system) at similar types of sources remains limited or is altogether not feasible. MONTANA-DAKOTA is unaware of an SCR system that has been installed at a source firing North Dakota lignite. Issues associated with SCR on lignite boilers are discussed in additional

detail in a 2009 study completed by the NDDH, which supports the limited feasibility of SCR.⁵ Additionally, physical space constraints at Heskett Station greatly limit the opportunity for SCR system equipment and tie-ins. Even so, for purposes of this review, MONTANA-DAKOTA has assumed that a low-dust SCR system could potentially be implemented at Unit 1 and has therefore included this in the four-factor analysis (even though it is considered by MONTANA-DAKOTA as technically infeasible). Based on current NO_x emissions, an SCR could potentially provide an additional NO_x reduction in the range of 70%-80%. Again, due to the issues stated above, we reserve the right to refine this analysis in the future if necessary.

2.1.3 Innovative Controls

NO_x controls grouped under the “Innovative Control Technologies” are not being considered in this analysis. These technologies are not considered commercially available and are not applicable at MONTANA-DAKOTA Heskett Station.

2.2 Factor 1 – The Cost of Compliance

The pollution control costs are presented on a dollar per ton of pollutant removed, calculated according to Equation 2.73 of the Cost Manual and 40 CFR 51, Appendix Y, Section IV, Subsection D. The cost effectiveness analysis compares the annualized cost of the technology per ton of pollutant removed and is evaluated on dollar per ton (\$/ton) basis using the annual operating cost (\$/yr) divided by the annual emissions reduction achieved by the control device (ton/yr). Additional details regarding the control equipment cost data and evaluation are noted in the control cost worksheets in Attachment A.

Table 2-2 NO_x Control Cost Evaluation for Heskett Station Unit 1

Control Technology	Estimated Control Efficiency (%)	Installed Capital Cost (\$)	Annualized Capital Cost (\$/yr)	Pollution Control Cost (\$/ton) ¹
SNCR	27%	\$4,180,000	\$744,000	\$9,100
Low-Dust SCR	80%	\$21,700,000	\$2,540,000	\$10,400

¹ The NDDH original BART ceiling costs were based on the June 1999 WRAP Annex to Grand Canyon Visibility Transport Report. Scaled to today's dollars, the average cost effectiveness threshold is approximately \$4,460 per ton.

SNCR and SCR are both considered economically infeasible for implementation at Unit 1 as the average cost effectiveness is not justified on a dollar per ton basis.

2.3 Factor 2 – Time Necessary for Compliance

Under Factor #2, the amount of time needed for full implementation of different control strategies is reviewed. Typically, the time necessary for compliance will include the time needed to develop and implement the regulation and/or the time needed to install the necessary emissions control equipment.

⁵ *Best Available Retrofit Technology – Selective Catalytic Reduction Technical Feasibility Analysis for North Dakota Lignite*. North Dakota Department of Health, Division of Air Quality. 7/1/2009

This analysis does not support the installation of any new retrofit NO_x emissions control methods at Heskett Station Unit 1 and therefore a review of the time necessary for compliance is not applicable.

2.4 Factor 3 – Energy and Non-Air Quality Environmental Impacts

Energy impacts are primarily related to the auxiliary power consumption of the SCR and SNCR systems and are included in the cost estimates under the variable annual costs. Other indirect energy impacts, such as the energy to produce reagents, are not considered in this study.

The operation of an SCR or SNCR system could have other non-air environmental impacts. For example, the storage of ammonia on-site creates the potential for accidents due to an ammonia release.

Depending on the type, concentration, and quantity of ammonia used, the material will be subject to regulation as a hazardous substance under the Comprehensive Environmental Response, Compensation, and Liability Act (CERCLA), Section 313 of the Emergency Planning and Community Right-to-Know Act, Section 112(r) of the CAA, and Section 311(b)(4) of the Clean Water Act.

2.5 Factor 4 – Remaining Useful Life of the Source

At this time, MONTANA-DAKOTA has assumed that the remaining useful life of the Unit 1 will be longer than the useful life of the emissions control measures evaluated in this analysis. Accordingly, as directed by the July 2006 EPA draft guidance, the useful life of the individual control measures is used to calculate emissions reductions, amortized costs, and cost effectiveness on a dollar per ton basis.

2.6 Proposed Controls and Emissions Rates

This analysis does not support the installation of any new retrofit NO_x emissions controls at Heskett Station Unit 1. The available and potential technically feasible control strategies (SCNR and SCR) are economically infeasible and have significant technical and other implementation concerns for commercial scale operation at a North Dakota lignite fired boiler. Therefore, MONTANA-DAKOTA is proposing to maintain current operational practices consistent with the parameters and limits included as part of the facility's existing Air Pollution Control Title V Permit to Operate (T5-F76001). Due to the uncertainty of the actual feasibility of NO_x emissions controls that was assumed as part of this four-factor analysis and the additional detailed analysis for cost refinement, MONTANA-DAKOTA reserve the right to refine this analysis in the future if necessary.

3 Unit 1 Sulfur Dioxide (SO₂) Four-Factor Analysis

Sulfur emissions from coal combustion consist primarily of SO₂, with a much lower quantity of sulfur trioxide (SO₃) and gaseous sulfates. These compounds form as the organic and pyritic sulfur in the coal is oxidized during the combustion process. The generation of SO₂ is directly related to the sulfur content and heating value of the fuel burned. The sulfur content and heating value of coal can vary dramatically depending on the source of the coal. Heskett Station uses North Dakota lignite and, for a short period in the past, used a blend of lignite and small amounts of Powder River Basin (PRB) coal as its fuel source.

3.1 SO₂ Emissions Control Measures

Several techniques can be used to reduce SO₂ emissions from coal combustion sources. SO₂ control techniques can be divided into pre- and post-combustion strategies.

Table 3-1 SO₂ Control Options with Potential Applications to Heskett Station Unit 1

Control Technology
Pre-Combustion Controls
<ul style="list-style-type: none">Fuel SwitchingFuel Washing
Post-Combustion SO ₂ Control Technologies
<ul style="list-style-type: none">Wet Flue Gas DesulfurizationDry Flue Gas Desulfurization<ul style="list-style-type: none">Spray Dryer AbsorberDry Sorbent Injection

3.1.1 Pre-Combustion Controls

A potential control strategy for reducing SO₂ emissions from a coal-fired boiler is to reduce the amount of sulfur contained in the coal. This can be accomplished through reducing inherent impurities via coal washing or potentially, more drastically, through switching to a lower sulfur fuel source.

In general, coal washing is accomplished by separating and removing inorganic impurities from organic coal particles. Inorganic impurities, including inorganic ash constituents and inorganic iron disulfide (FeS₂ or pyrite), are typically denser than the coal particles. This property is generally used in a wet cleaning process to separate coal particles from the inorganic impurities.

While washing may be effective in removing rock inclusions from coal, including sulfur-bearing pyrites, a significant amount of coal may also be lost in the washing process requiring the mine to process significantly more coal to make up for coal lost in the washing process. Further, an inherent consequence of coal washing is the generation of wastewater and solid waste streams.

No information was identified regarding the washability, or effectiveness of washing, lignite or subbituminous PRB coals, and it is unlikely that coal washing will result in a significant decrease in

controlled SO₂ emissions. Therefore, coal washing is not considered a technically feasible or commercially available retrofit control option at Heskett Station.

North Dakota lignite has a relatively high moisture content, low heating value, and low sulfur content. PRB coal typically also has relatively lower heating values compared to other fuel sources but lower sulfur content than lignite. In theory, if a boiler could utilize it for fuel and a fuel feed system could receive it; burning 100% PRB would result in lower uncontrolled SO₂ emissions rates. However, lower uncontrolled emissions rates do not necessarily translate into lower controlled emissions rates. The efficiency of pollution control equipment is a function of several operating variables, including the uncontrolled pollutant concentration. At a lower uncontrolled pollution concentration, it becomes more difficult to maintain a high emissions control efficiency.

Unit 1 is designed for lignite combustion and cannot burn 100% PRB without significant boiler modifications, including changes to the internal boiler materials of construction and modifications to provide flue gas recirculation. The amount of tube surface area required for lignite combustion is much larger than needed for PRB combustion. Burning even high blends of PRB would result in increased furnace temperatures that are too high and require changes to the superheater (and other boiler tubes) and changes to keep fly ash from becoming molten and fouling the boiler. Further, the viability of the Heskett Station is dependent upon an economic supply of fuel. As a result, switching to burning a lower sulfur subbituminous coal in amounts is not supported by the existing equipment and is not considered a technically feasible option for Heskett Station Unit 1.

3.1.2 Post-Combustion Controls

Post-combustion controls or flue gas desulfurization (FGD) systems commonly used to control SO₂ emissions can be classified as either wet or dry systems. Both systems rely on creating turbulence in the gas stream to increase contact with the absorbing medium. Wet systems are commonly capable of achieving higher removal efficiencies than dry systems because it is easier to mix a gas with a liquid than a solid. FGD requires the use of an alkali powder slurry, and lime (or limestone) as the most widely used compound for acid gas absorption. Sodium based reagents are also available, and while they provide better SO₂ solubility, they are significantly more expensive.

Wet FGD systems may discard all the waste by-product streams or regenerate and reuse them. Wet systems generally require more extensive networks of pumps and piping than dry systems to recirculate, collect and treat the scrubbing liquid. As implied by the name, dry scrubbers require less water than wet systems but also require higher temperatures to ensure that all moisture has been evaporated before leaving the scrubber. There are many available FGD systems including wet scrubbing, spray dryer absorption, and dry sorbent injection.

3.1.2.1 Wet Lime/Limestone Scrubbing

Wet lime/limestone scrubbing involves scrubbing the exhaust gas stream with a slurry comprised of lime (CaO) or limestone (CaCO₃) in suspension. The process takes place in a wet scrubbing tower located downstream of a particular matter (PM) control device to prevent the plugging of spray nozzles and other

problems caused by the presence of particulates in the scrubber. The SO_2 in the gas stream reacts with the lime or limestone slurry to form calcium sulfite ($\text{CaSO}_3 \cdot 2\text{H}_2\text{O}$) and calcium sulfate (CaSO_4).

Physical space constraints at Heskett Station greatly limit the opportunity for construction and operation of an add-on control equipment such as wet gas scrubber system. However, for purposes of this analysis, a wet scrubber is considered a technically feasible retrofit control option. It is assumed, based on available information, that the wet FGD system would be able achieve an SO_2 emissions reduction of approximately 99%.⁶

Control efficiencies assumed achievable for purposes of this analysis are considered conservative due to being based on operation at high load conditions. The high rate of assumed capture may not be achieved at low load operation. Installation of a wet scrubbing system would require removal of the existing dry electrostatic precipitator (ESP) control system. Environmental and cost implications associated with said required retrofit have not been included as part of the analysis at this time. MONTANA-DAKOTA reserves the right to refine the assumptions and impacts to the cost of controls if further study is needed.

3.1.2.2 Spray Dry Absorption (SDA)

Spray dry absorption (SDA) is a dry scrubbing system that sprays a fine mist of lime slurry into an absorption tower where the SO_2 is absorbed by the droplets. The absorption of the SO_2 leads to the formation of calcium sulfite ($\text{CaSO}_3 \cdot 2\text{H}_2\text{O}$) and calcium sulfate (CaSO_4).

The liquid-to-gas ratio is such that the heat from the exhaust gas causes the water to evaporate before the droplets reach the bottom of the tower. This leads to the formation of a dry powder that is carried out with the gas and collected with a fabric filter. The process equipment associated with a spray dryer typically includes an alkaline storage tank, mixing and feed tanks, an atomizer, spray chamber, particulate control device and a recycle system.

Designing an SDA for an existing unit presents significant design challenges. The SDA must be located upstream of the unit's particulate matter control device and the reactor vessel must be located within existing site parameters. Retrofitting Heskett Station Unit 1 with an SDA would require extensive ductwork to direct flue gas flow from the boiler to the SDA and back to the ESP. An SDA will require additional unreacted hydrated lime to the flue gas and increase particulate loading to the particulate control device. Second, to maximize utilization of the lime reactant (which is more expensive compared to limestone), the system must be designed with a solids recycling system to mix some of the controlled particulate solids product with fresh lime slurry and re-inject the mixture into the SDA. The Unit would need an in-depth study, including a full review of the existing ESP's ability to accept and properly clean the flue gas, to determine if truly feasible. Historically, SDA systems have typically been permitted as best available controls on pulverized coal-fired boilers firing low-sulfur PRB coal. Nevertheless, for purposes of this analysis, SDA is considered a technically feasible retrofit control option. It was been assumed that a

⁶ <https://www3.epa.gov/ttn/catc/dir1/fsprytwr.pdf>

baghouse, requiring retrofit of the existing particulate matter control system, would be required for proper operation and particulate matter control.

SDA control efficiency is typically in the 70% to 90% range. The high rate of assumed capture may not be achieved at low load operation. Due to expected low load operation and other unknowns, MONTANA-DAKOTA has assumed a control efficiency of 70%. MONTANA-DAKOTA reserves the right to refine the assumptions and impacts to the cost of controls if further study is needed.

3.1.2.3 Dry Sorbent Injection (DSI)

Dry sorbent injection (DSI) involves the injection of a lime or limestone powder into the exhaust gas stream. The stream is then passed through a baghouse to remove the sorbent and entrained SO₂. The process was developed as a lower cost FGD option because the mixing occurs directly in the exhaust gas stream instead of in a separate tower. DSI systems are simple systems, and generally require a sorbent storage tank, feeding mechanism, transfer line and blower, and an injection device. The dry sorbent is typically injected countercurrent to the gas flow. An expansion chamber is often located downstream of the injection point to increase residence time and efficiency. Particulates generated in the reaction are controlled in the systems particulate control device. Depending on the residence time and gas stream temperature, sorbent injection control efficiency is typically between 50% and 70%. Although a dry sorbent injection system may be technically feasible at Unit 1, it is not practical to assume a high level of control efficiency would be achievable due to space constraints limiting the reaction time. Further, Unit 1 exhaust gas temperature is higher (420°F) than the ideal gas stream temperature range of 300°F to 350°F and the impact on control efficiency would require further evaluation. For purposes of this analysis MONTANA-DAKOTA has assumed a control efficiency of 50% and that the existing ESP could not handle additional loading, requiring retrofit of the existing particulate matter control system for proper operation and particulate matter control.

DSI is considered a technically feasible retrofit control option for this analysis, but due to space constraints and other issues, MONTANA-DAKOTA reserves the right to more analysis in the future to determine actual feasibility with the Unit. A full review of the ESP's ability to accept and properly clean the flue gas with changed properties would be needed to determine feasibility and possible costs. MONTANA-DAKOTA reserves the right to refine the assumptions and impacts to the cost of controls if further study is needed.

3.2 Factor 1 – The Cost of Compliance

The pollution control costs are presented on a dollar per ton of pollutant removed calculated according to Equation 2.73 of the Cost Manual and 40 CFR 51, Appendix Y, Section IV, D. The cost effectiveness compares the annualized cost of the technology per ton of pollutant removed and is evaluated on dollar per ton (\$/ton) basis using the annual operating cost (\$/yr) divided by the annual emissions reduction achieved by the control device (ton/yr). Additional details regarding the control equipment cost data and evaluation are noted in the control cost worksheets in Attachment B.

Table 3-2 SO₂ Control Cost Evaluation for Heskett Station Unit 1

Control Technology	Estimated Control Efficiency (%)	Installed Capital Cost (\$)	Annualized Capital Cost (\$/yr)	Pollution Control Cost (\$/ton)
Wet Scrubber	98%	\$71,500,000	\$10,300,000	\$5,100
Spray Dry Absorption	70%	\$55,700,000	\$8,000,000	\$5,600
Dry Sorbent Injection	50%	\$32,300,000	\$5,150,000	\$5,100

¹ The NDDH original BART ceiling costs were based on the June 1999 WRAP Annex to Grand Canyon Visibility Transport Report. Scaled to today's dollars, the average cost effectiveness threshold is approximately \$4,460 per ton.

The SO₂ control options evaluated as part of this analysis are considered economically infeasible for implementation at Unit 1; costs are not justified on a dollar per ton basis.

3.3 Factor 2 – Time Necessary for Compliance

Under Factor #2, the amount of time needed for full implementation of different control strategies is reviewed. Typically, time for compliance includes the time needed to develop and implement the regulation and/or the time needed to install the necessary emissions control equipment. This analysis does not support the installation of any new retrofit SO₂ emissions controls at Heskett Station Unit 1 and therefore a review of the time necessary for compliance is not applicable.

3.4 Factor 3 – Energy and Non-Air Quality Environmental Impacts

The energy and non-air environmental impacts associated with implementation of the above-identified SO₂ control measures are discussed in the following sections.

3.4.1 Wet Lime/Limestone Scrubbing

In addition to the economic impacts of a wet FGD system, there are several collateral environmental impacts associated with its operation. Wet FGD systems generate a calcium sulfate waste by-product that must be properly managed. Historically, solid wastes generated from wet FGD systems have been dewatered and disposed of in landfills. Most new wet FGD systems utilize a forced oxidation system that results in a gypsum by-product that can sometimes be sold into the local gypsum market. If an adequate local gypsum market is not available, the gypsum by-product will require proper disposal. Currently, there is not a viable market in proximity to Heskett Station and usable quantity would be likely limited. A study of disposal at our current facility would be required and, if feasible, additional permitting needed. If not acceptable for sale, disposal costs may be significant and would have to include transport costs. In a northern climate this may be a significant issue.

A wet FGD system will also result in greater particulate matter emissions. Wet FGD systems must be located downstream of the unit's particulate control device; therefore, dissolved solids from the wet FGD system will be emitted with the wet FGD moisture plume. In addition, any SO₃ remaining in the flue gas could react with moisture in the wet FGD to generate sulfuric acid mist.

Wet FGD systems also require significantly more water than dry FGD systems or limestone injection systems. Wet FGD control systems typically require approximately 1.0 gpm of water per gross MW output.

Additional costs may result from a potential need to increase Heskett Station's existing water rights for withdrawal of water. Finally, wet FGD systems generate a wastewater stream that must be treated and discharged in compliance with Effluent Limitations Guidelines for electric steam generating units. The site faces challenges for space due to rail lines, historical disposal and archeological issues. Coal combustion residual (CCR) considerations would need to be evaluated (including location restrictions); state and federal discharge permitting requirements (from the new system) would also be applicable. These would take significant study and time.

3.4.2 Dry Flue Gas Desulfurization (FGD)

Collateral environmental impacts are less significant with dry scrubbing systems. Using a dry FGD system at Unit 1 requires the facility to handle two reactants; limestone for injection in the AFBC (Unit 2) and pebble lime for use in the dry scrubber. The receipt, storage, management and use of two reactants will result in increased material handling PM emissions.

Lime used in dry FGD systems must be hydrated prior to use, increasing the facility's overall consumption of water. However, water used to hydrate the lime reactant is evaporated in the dry scrubbing system, eliminating the need for additional wastewater treatment and discharge.

3.5 Factor 4 – Remaining Useful Life of the Source

At this time, MONTANA-DAKOTA has assumed that the remaining useful life of the Unit 1 will be longer than the useful life of the emissions control measures evaluated in this analysis. Accordingly, as directed by the July 2006 EPA draft guidance, the useful life of the individual control measures is used to calculate emissions reductions, amortized costs and cost effectiveness on a dollar per ton basis. MONTANA-DAKOTA relied on EPA's Control Cost Manual to determine the appropriate value for use in the evaluation (20 years).

3.6 Proposed Controls and Emissions Rates

This analysis does not support the installation of any new retrofit SO₂ emissions controls at Heskett Station Unit 1. The available and potential technically feasible control strategies are economically infeasible and have significant technical and other concerns for operation Heskett Station. Therefore, MONTANA-DAKOTA is proposing to maintain current operational practices consistent with the parameters and limits included as part of the facility's existing Air Pollution Control Title V Permit to Operate (T5-F76001). Due to the uncertainty of the actual performance of the potentially available control technologies evaluated, the uncertainty of technically feasible SO₂ emissions controls that we assumed as part of this four-factor analysis, the implementation concerns and the additional detailed analysis for cost refinement, MONTANA-DAKOTA reserves the right to refine this analysis in the future if necessary.

4 Unit 2 Nitrogen Oxides (NOx) Four-Factor Analysis

There are three mechanisms by which NOx production occurs: thermal, fuel and prompt NOx. Fuel bound NOx is a primary concern with solid and liquid fuel combustion sources; it is formed as nitrogen compounds in the fuel are oxidized in the combustion process. The secondary mechanism of NOx production is through thermal NOx formation. This mechanism arises from the thermal dissociation of nitrogen and oxygen molecules in combustion air. The thermal oxidation reaction is as follows:

Downstream of the flame, significant amounts of NO₂ can be formed when NO is mixed with air. The reaction is as follows:

Thermal oxidation is a function of the residence time, concentration of combustion gases (primarily nitrogen and oxygen) in the inlet air, and peak reaction temperature. Prompt NOx is a form of thermal NOx which is generated at the flame boundary. It is the result of reactions between nitrogen and carbon radicals generated during combustion. Only minor amounts of NOx are emitted as prompt NOx.

4.1 NOx Emissions Control Measures

There are several potentially available methods to control NOx emissions, as show in Table 4-1, however not all are applicable for implementation at Unit 2. Accordingly, as part of this four-factor analysis, MONTANA-DAKOTA has narrowed the list of NOx control technology options for review to those that are truly applicable for a retrofit installation at the Heskett Station Unit 2. The NOx retrofit control options are identified based on a review of available technical information.

Retrofit NOx control technologies can be divided into two general categories: (1) combustion controls, and (2) post-combustion controls. Combustion controls reduce the amount of NOx that is generated in the boiler, while post-combustion controls remove NOx from the boiler exhaust gas.

Table 4-1 List of Potentially Available Retrofit NOx Control Options

4.1.1 Combustion Controls

The rate of NOx formation in the combustion zone is a function of free oxygen, peak flame temperature and residence time. Combustion techniques designed to minimize the formation of NOx will minimize one or more of these variables. Combustion control considered Heskett Station Unit 2 are summarized below.

4.1.1.1 Fluidized Bed Combustion (FBC)

Fluidized bed combustion offers the potential for lower NOx emissions due to inherently lower combustion temperatures. In an atmospheric fluidized bed combustion (AFBC) boiler, like Unit 2, fuel is burned in a bed of hot combustible particles suspended by an upward flow of combustion air. The fuel (coal) can be mixed with an inert sand or limestone (used for SO₂ control) to form the combustion bed. Bed temperatures are usually maintained around 1550°F to 1750°F because this temperature is optimal for the chemical processes needed to capture SO₂ and control NOx emissions. Efficient combustion in the AFBC is achieved because of the relatively long residence time of fuel in the bed and good gas/fuel contact. At the low combustion temperatures, the formation of thermal NOx is essentially eliminated; however, nearly all of the fuel nitrogen will be converted to nitrogen oxides. Unit 2 is an AFBC boiler and has inherently different properties than the typical FBC.

4.1.1.2 Low NOx Burners (LNB)

Low NOx burner (LNB) technology utilizes advanced burner design to reduce NOx formation through the restriction of oxygen, flame temperature, and/or residence time. LNB is a staged combustion process that is designed to split fuel combustion into two zones. In the primary zone, NOx formation is limited by either one of two methods. Under staged air rich (high fuel) condition, low oxygen levels limit flame temperatures resulting in less NOx formation. The primary zone is then followed by a secondary zone in which the incomplete combustion products formed in the primary zone act as reducing agents. Alternatively, under staged fuel lean (low fuel) conditions, excess air will reduce flame temperature to reduce NOx formation. In the secondary zone, combustion products formed in the primary zone act to lower the local oxygen concentration, resulting in a decrease in NOx formation. Low NOx burners typically achieve NOx emissions reductions of 25% to 50%.

AFBC boilers do not use burners during normal operation, as combustion takes place within the fluidized bed. Therefore, LNB combustion control technologies are not technically feasible, and not applicable to Heskett Station Unit 2.

4.1.1.3 Overfire Air (OFA)

Overfire air (OFA) diverts a portion of the total combustion air from the burners and injects it through separate air ports above the top level of burners. OFA is the typical NOx control technology used in lignite-fired boilers and is primarily geared to thermal NOx reductions. Staging of the combustion air creates an initial fuel-rich combustion zone for a cooler fuel-rich combustion zone. This reduces the production of thermal NOx by lowering combustion temperature and limiting the availability of oxygen in the combustion zone where NOx is most likely to be formed.

Heskett Station Unit 2 is currently designed with nominal staged combustion. The boiler is designed with one row of OFA ports located on the front and back wall of the furnace. Both banks of OFA ports are located relatively low in the furnace, just above the coal feeder systems and combustion bed. The degree of staging is unit-specific, and limited by operational problems since the staged combustion could result in conditions that favor incomplete combustion. Adding additional staged combustion would require the installation of more OFA ports above the existing ports or on the furnace sidewalls. Retrofitting an existing boiler with OFA ports can be challenging, and MONTANA-DAKOTA may be required to model flow within the boiler to ensure new OFA ports are properly located to provide staged combustion air. Adding OFA ports may also require the installation of additional booster fans to support mixing of the air and flue gas.

Moreover, thermal NOx emissions are essentially eliminated as a result of the AFBC, and it is therefore unlikely that additional staged combustion/OFA would result in any further significant NOx reductions. For these reasons, MONTANA-DAKOTA considers adding additional staged combustion is not technically feasible for additional NOx control at Heskett Station Unit 2.

4.1.1.4 External Flue Gas Recirculation (FGR)

Flue gas recirculation (FGR) is a flame-quenching technique that involves recirculating a portion of the flue gas from the economizer or air heater outlet and returning it to the furnace through the burner or windbox. The primary effect of FGR is to reduce the peak flame temperature through adsorption of the

combustion heat by the relatively inert flue gas, and to reduce the oxygen concentration in the combustion zone. FGR reduces thermal NO_x generation in high-temperature emissions sources.

Additional ductwork and a blower would be required to recirculate flue gas. These elements must fit in the limited space around the burner. The space constraints and the lowered flame temperature created by FGR make it incompatible with the existing combustion controls on Units 2. To integrate a blower and inject flue gas into the combustion zone of the existing unit would require a full design review and likely costly modifications to the existing combustion control scheme. To date, MONTANA-DAKOTA is unaware of another lignite fired AFBC boiler utilizing FGR technology. Further, the addition of FGR could further result in reduced boiler capacity. Flue gas recirculation is therefore a technically infeasible control option and is not be considered further.

4.1.1.5 Burner Tempering (Water Injection)

The principle behind combustion tempering is to inject an atomized water spray into the high NO_x production zones of the furnace flame. The water spray reduces the temperature within the zone, resulting in lower NO_x production within the zone. Burner tempering has been used on wall- and tangential-fired pulverized coal-fired units. The risk of any water so close to the bed material that would form concretions and encase our boiler tubes in the bed is immediately concerning.

However, FBC boilers do not use burners during normal operation, and burner tempering would not be applicable to FBC units. Therefore, burner tempering is not a technically feasible NO_x control technology for Unit 2 and is not considered further.

4.1.2 Post-combustion Controls

NO_x can be reduced to N₂ in add-on systems located downstream of the furnace area of the combustion process. The two main techniques in commercial service include the selective non-catalytic reduction (SNCR) process and the selective catalytic reduction (SCR) process. There are a number of different process systems in each of these categories of control techniques.

In addition to these treatment systems, there are a large number of other processes being developed and tested on the market. These approaches involve innovative techniques of chemically reducing, absorbing, or adsorbing NO_x downstream of the combustion chamber. One example of these alternatives is nonselective catalytic reduction (NSCR).

4.1.2.1 Selective Non-Catalytic Reduction (SNCR)

In the selective non-catalytic reduction (SNCR) process, urea or ammonia-based chemicals are injected into the flue gas stream to convert NO to N₂ and water. SNCR control efficiency is typically 25% to 50%. Without the participation of a catalyst, the reaction requires a high temperature range to obtain activation energy. The relevant reactions are as follows:

At temperature ranges of 1470°F to 1830°F, reaction (1) dominates. At temperatures above 2000°F, reaction (2) will dominate. Flue gas temperature at the point of reagent injection can greatly affect removal efficiencies and the quantity of NH₃ that will pass through unreacted (ammonia slip). At temperatures below the desired operating range, the NO_x reduction reactions diminish and unreacted NH₃ emissions increase. Above the desired temperature range, NH₃ is oxidized to NO_x resulting in low NO_x reduction efficiencies.

Mixing of the reactant and flue gas within the reaction zone is also an important factor to SNCR performance. The SNCR system must be designed to deliver the reagent in the proper temperature window, and allow sufficient residence time of the reagent and flue gas in that temperature window. In addition to temperature, mixing, and residence time, several other factors influence the performance of an SNCR system including reagent-to-NO_x ratio and NO_x concentration in the flue gas.

SNCR systems are capable of achieving a NO_x emissions reduction as high as 50 to 60 percent in optimum conditions (adequate reaction time, temperature, and reagent/ flue gas mixing, high baseline NO_x conditions, multiple levels of injectors) with ammonia slips of 10 to 50 ppmvd. Typically, optimum conditions are difficult to achieve, resulting in emissions reduction levels of 20 to 40 percent. Potential performance is very site-specific and varies with fuel type, steam generator size, allowable ammonia slip, furnace CO concentrations, and steam generator heat transfer characteristics.

The application of SNCR to Heskett Station Unit 2 has the potential to be technically feasible because furnace temperatures are assumed (note that there is not instrumentation currently in place to measure temperature) to be within the temperature window needed for NO_x reduction, and flue gas mixing and residence time within the boiler should promote the reaction kinetics. However, the effectiveness of an SNCR system at Heskett Station Unit 2 would be limited because of the design and boiler operating temperatures. The optimal condition locations are small due to the boiler size and type and a boiler study would be required to more correctly predict feasibility and effectiveness at Unit 2. Even so, for purposes of this review, MONTANA-DAKOTA has assumed that SNCR could potentially be implemented at Unit 2 and has therefore included this in the four-factor analysis. Based on the calculated default control efficiency from EPA, a SNCR could potentially provide a NO_x reduction of approximately 27% at Unit 2. As mentioned in the discussion of Unit 1, with the uncertainty due to limited space and other issues, we reserve the right to refine this analysis in the future if necessary. A full review of the ESP's ability to accept and properly clean the flue gas with changed properties would be needed to determine feasibility and possible costs.

4.1.2.2 Selective Catalytic Reduction (SCR)

Selective catalytic reduction (SCR) is a post combustion NO_x control technology in which NH₃ is injected into the flue gas stream in the presence of a catalyst. SCR control efficiency is typically 70% to 90%. NO_x is removed through the following chemical reaction:

The catalyst bed lowers the activation energy required for NO_x decomposition. The catalyst contains an active phase, such as vanadium pentoxide, on a carrier, such as titanium dioxide, and these are used for their ability to lower the activation energy required for NO_x decomposition. SCR requires an optimum temperature range of 650 to 800°F.

A “high-dust” SCR arrangement in which the reactor is located between the outlet of the economizer and the inlet of the air heater and upstream of particulate control is typically the preferred arrangement where technically feasible. These arrangements typically require soot blowers for catalyst cleaning. In a “low-dust” arrangement, the SCR reactor is located after the particulate control device. This arrangement is preferred when the fly ash contains a high level of contaminants that would block catalyst actions, and removing most of the fly ash from the flue gas will help prolong the catalyst life. Firing ND lignite coal that contains high amounts of organically bound inorganics (and has a higher total sodium content), results in a stream heavily laden with particulate matter and sodium that combine to plug (block) catalyst passages. Due to the likelihood of catalyst plugging and the ability of phosphorus, sodium, other alkali and alkaline earth cations organically bound in ND lignite to mask (or blind) a catalyst and its reactions if not fully plugged, a high-dust SCR system is considered technically infeasible on both Units 1 and 2. A low-dust SCR (downstream of particulate control), would require reheat to bring the stream temperature back to the effective control range after it is cooled for particulate removal. There would still be important concerns with this arrangement due to the contaminants’ unique properties to inhibit the catalyst from operating, but in theory, the issues would be less than with a high-dust system.

Although it would appear to be a potentially a technically feasible control option, MONTANA-DAKOTA notes that installing SCR (even a low-dust system) at similar types of sources remains limited or is altogether not feasible. MONTANA-DAKOTA is unaware of an SCR system that has been installed at a source firing North Dakota lignite. Issues associated with SCR on lignite boilers are discussed in additional detail in a 2009 study completed by the NDDH that supports the limited feasibility of SCR.⁷ Additionally, physical space constraints at Heskett Station greatly limit the opportunity for SCR system equipment and tie-ins. Even so, for purposes of this review, MONTANA-DAKOTA has assumed that a low-dust SCR system could potentially be implemented at Unit 2 and has therefore included this in the four-factor analysis (even though it is considered by MONTANA-DAKOTA as technically infeasible). Based on current NO_x emissions, an SCR could potentially provide an additional NO_x reduction in the range of 70%-80%. As mentioned before, we reserve the right to refine this analysis in the future if necessary.

4.1.3 Innovative Controls

NO_x controls grouped under the “Innovative Control Technologies” are not being considered in this analysis. These technologies are not considered commercially available and are not applicable at MONTANA-DAKOTA Heskett Station.

⁷ *Best Available Retrofit Technology – Selective Catalytic Reduction Technical Feasibility Analysis for North Dakota Lignite*. North Dakota Department of Health, Division of Air Quality. 7/1/2009

4.2 Factor 1 – The Cost of Compliance

The pollution control costs are presented on a dollar per ton of pollutant removed calculated according to Equation 2.73 of the Cost Manual and 40 CFR 51, Appendix Y, Section IV, D. The cost effectiveness analysis compares the annualized cost of the technology per ton of pollutant removed and is evaluated on dollar per ton (\$/ton) basis using the annual operating cost (\$/yr) divided by the annual emissions reduction achieved by the control device (ton/yr). Additional details regarding the control equipment cost data and evaluation are noted in the control cost worksheets in Attachment A.

Table 4-2 NOx Control Cost Evaluation for Heskett Station Unit 2

Control Technology	Estimated Control Efficiency (%)	Installed Capital Cost (\$)	Annualized Capital Cost (\$/yr)	Pollution Control Cost (\$/ton)
Low-Dust SCR	80%	\$41,600,000	\$5,630,000	\$6,100
SNCR	27%	\$5,000,000	\$1,680,000	\$5,300

¹ The NDDH original BART ceiling costs were based on the June 1999 WRAP Annex to Grand Canyon Visibility Transport Report. Scaled to today's dollars, the average cost effectiveness threshold is approximately \$4,460 per ton.

SNCR and SCR are both considered economically infeasible for implementation at Unit 2 as the average cost effectiveness is not justified on a dollar per ton basis.

4.3 Factor 2 – Time Necessary for Compliance

Under Factor #2, the amount of time needed for full implementation of different control strategies is reviewed. Typically, the time necessary for compliance includes the time needed to develop and implement the regulation and/or the time needed to install the necessary emissions control equipment. This analysis does not support the installation of any new retrofit NOx emissions control methods at Heskett Station Unit 2 and therefore a review of the time necessary for compliance is not applicable.

4.4 Factor 3 – Energy and Non-Air Quality Environmental Impacts

Energy impacts are primarily related to the auxiliary power consumption of the SCR and SNCR systems and are included in the cost estimates under the variable annual costs. Other indirect energy impacts, such as the energy to produce reagents, are not considered in this study.

The operation of an SCR or SNCR system could have other non-air environmental impacts. For example, the storage of ammonia on-site creates the potential for accidents due to an ammonia release. Depending on the type, concentration, and quantity of ammonia used, the material will be subject to regulation as a hazardous substance under CERCLA, Section 313 of the Emergency Planning and Community Right-to-Know Act, Section 112(r) of the CAA, and Section 311(b)(4) of the Clean Water Act.

4.5 Factor 4 – Remaining Useful Life of the Source

At this time, MONTANA-DAKOTA has assumed that the remaining useful life of the Unit 2 will be longer than the useful life of the emissions control measures evaluated in this analysis. Accordingly, as directed

by the July 2006 EPA draft guidance, the useful life of the individual control measures is used to calculate emissions reductions, amortized costs and cost effectiveness on a dollar per ton basis.

4.6 Proposed Controls and Emissions Rates

This analysis does not support the installation of any new retrofit NO_x emissions controls at Heskett Station Unit 2. The available and potential technically feasible control strategies (SNCR and SCR) are economically infeasible and have significant technical and other concerns for commercial scale operation at a lignite fired boiler. Therefore, MONTANA-DAKOTA is proposing to maintain current operational practices consistent with the parameters and limits included as part of the facility's existing Air Pollution Control Title V Permit to Operate (T5-F76001). As mentioned in the discussion under Unit 1, with the uncertainty of the actual feasibility for implementation of the NO_x controls evaluated as part of this four-factor analysis and the required additional cost refinement evaluation, MONTANA-DAKOTA reserves the right to refine this analysis in the future if necessary.

5 Unit 2 Sulfur Dioxide (SO₂) Four-Factor Analysis

Sulfur emissions from coal combustion consist primarily of SO₂, with a much lower quantity of SO₃ and gaseous sulfates. These compounds form as the organic and pyritic sulfur in the coal is oxidized during the combustion process. The generation of SO₂ is directly related to the sulfur content and heating value of the fuel burned. The sulfur content and heating value of coal can vary dramatically depending on the source of the coal. Heskett Station uses North Dakota lignite and, in the past, had occasionally used a blend of lignite and PRB coal as its fuel source.

5.1 SO₂ Emissions Control Measures

Several techniques can be used to reduce SO₂ emissions from coal combustion sources. SO₂ control techniques can be divided into pre- and post- combustion strategies.

Table 5-1 SO₂ Control Options with Potential Applications to Heskett Station Unit 2

Control Technology
Pre-Combustion Controls
<ul style="list-style-type: none">Fuel SwitchingFuel Washing
Combustion Control: Limestone injection at existing AFCB
Post-Combustion SO ₂ Control Technologies
<ul style="list-style-type: none">Wet Flue Gas DesulfurizationDry Flue Gas Desulfurization<ul style="list-style-type: none">Spray Dryer AbsorberDry Sorbent Injection

5.1.1 Pre-Combustion Controls

A potential control strategy for reducing SO₂ emissions from a coal-fired boiler is to reduce the amount of sulfur contained in the coal. This can be accomplished through reducing inherent impurities via coal washing or potentially, more drastically, through switching to a lower sulfur fuel source. Coal washing is discussed above in Section 3.1.

As also noted above, North Dakota lignite has a relatively high moisture content, low heating value, and low sulfur content. PRB coal typically also has relatively lower heating values compared to other fuel sources but lower sulfur content than lignite. In theory, if a boiler could utilize it for fuel and a fuel feed system could receive it; burning 100% PRB would result in lower uncontrolled SO₂ emissions rates. However, lower uncontrolled emissions rates do not necessarily translate into lower controlled emissions rates. The efficiency of pollution control equipment is a function of several operating variables, including the uncontrolled pollutant concentration. At a lower uncontrolled pollution concentration, it becomes more difficult to maintain a high emissions control efficiency.

MONTANA-DAKOTA has studied the feasibility of firing lower sulfur PRB coal at Unit 2. Test burns conducted at Heskett Station Unit 2 indicated that significant boiler modifications, including changes to the internal boiler materials of construction and modifications to provide flue gas recirculation, would be needed to fire 100% PRB. Based on these test burns, the Unit 2 boiler is limited to firing a limited amount of PRB. Unit 2 is designed to fire lignite and any coal viability implemented for short periods of time is dependent upon an economic supply of fuel. Switching to PRB would require significant boiler modifications, essentially replacing and rebuilding the boiler internals and combustion control systems. Therefore, switching to burning a lower sulfur subbituminous coal in amounts not supported by the existing equipment is not considered a technically feasible option for Unit 2.

Additionally, PRB is not currently offered in a size that Heskett Station is able to receive and process, meaning the facility cannot accept fuel or get it to the boiler without significant modifications and equipment changes.

5.1.2 Combustion Controls: Limestone Injection at AFBC

Heskett Station has implemented a limestone addition to the sand bed for Unit 2 for RH emissions reductions in 2017. An SO₂ limit of 0.60 lb/MMBtu was applied to Unit 2 and Heskett Station has demonstrated compliance with this 12-month rolling average limit. Unit 2 has been operating at a mid to low load range over the past two to three years (a recent load range report indicates 52-66 MW for 95% of the time, only 5% operation at higher load of about 72 MW). During the same timeframe, our compliance with the 12-month rolling average was 0.46 lb/MMBtu. The relatively low 12-month rolling average compliance values represent operation at a lower load range and does not indicate improved capture efficiency that would occur within the mid to high load range as confirmed in our optimization study. All SO₂ emissions limits currently imposed from utilization of limestone for SO₂ control should remain unchanged.

5.1.3 Post-Combustion Controls

Post-combustion controls or FGD systems commonly used to control SO₂ emissions can be classified as either wet or dry systems. Both systems rely on creating turbulence in the gas stream to increase contact with the absorbing medium. Wet systems are commonly capable of achieving higher removal efficiencies than dry systems because it is easier to mix a gas with a liquid than a solid. FGD requires the use of an alkali powder slurry, with lime (or limestone) as the most widely used compound for acid gas absorption. Sodium based reagents are also available, and while they provide better SO₂ solubility, they are significantly more expensive.

Wet FGD systems may discard all of the waste by-product streams or regenerate and reuse them. Wet systems generally require more extensive networks of pumps and piping than dry systems to recirculate, collect, and treat the scrubbing liquid. As implied by the name, dry scrubbers require less water than wet systems but also require higher temperatures to ensure that all moisture has been evaporated before leaving the scrubber. There are many available FGD systems including wet scrubbing, spray dryer absorption, and dry sorbent injection.

5.1.3.1 Wet Lime/Limestone Scrubbing

Wet lime/limestone scrubbing involves scrubbing the exhaust gas stream with a slurry comprised of CaO or CaCO₃ in suspension. The process takes place in a wet scrubbing tower located downstream of a PM control device to prevent the plugging of spray nozzles and other problems caused by the presence of particulates in the scrubber. The SO₂ in the gas stream reacts with the lime or limestone slurry to form calcium sulfite (CaSO₃•2H₂O) and calcium sulfate (CaSO₄).

Physical space constraints at Heskett Station greatly limit the opportunity for construction and operation of an add-on control equipment such as wet gas scrubber system. However, for purposes of this analysis, a wet scrubber is considered a technically feasible retrofit control option. It will be assumed, based on available information, that the wet FGD system would be able achieve an SO₂ emissions reduction of approximately 99%.⁸

Control efficiencies assumed achievable for purposes of this analysis are conservative due to being based on operation at high load conditions. The high rate of assumed capture may not be achieved at low load operation. MONTANA-DAKOTA reserves the right to refine the assumptions and impacts to the cost of controls if further study is needed. A full review of the ESP's ability to accept and properly clean the flue gas with changed properties would be needed to determine feasibility and possible costs. MONTANA-DAKOTA reserves the right to refine the assumptions and impacts to the cost of controls if further study is needed.

5.1.3.2 Spray Dry Absorption (SDA)

Spray dry absorption (SDA) is a dry scrubbing system that sprays a fine mist of lime slurry into an absorption tower where the SO₂ is absorbed by the droplets. The absorption of the SO₂ leads to the formation of calcium sulfite (CaSO₃•2H₂O) and calcium sulfate (CaSO₄).

The liquid-to-gas ratio is such that the heat from the exhaust gas causes the water to evaporate before the droplets reach the bottom of the tower. This leads to the formation of a dry powder that is carried out with the gas and collected with a fabric filter. The process equipment associated with a spray dryer typically includes an alkaline storage tank, mixing and feed tanks, an atomizer, spray chamber, particulate control device and a recycle system.

Designing an SDA for an existing unit presents significant design challenges. The SDA must be located upstream of the unit's particulate matter control device, at a point where the flue gas is already laden with combustion ash, calcium sulfite solids, and unreacted lime from the combustion bed (assuming lime or limestone is used as the bed material). The reactor vessel must also be located within existing site parameters requiring extensive ductwork to direct flue gas flow from the boiler to the SDA and back to the ESP. An SDA will add additional unreacted hydrated lime to the flue gas, and increase particulate loading to the particulate control device. Second, to maximize utilization of the lime reactant (which is expensive compared to limestone), the system must be designed with a solids recycling system to mix

⁸ <https://www3.epa.gov/ttn/catc/dir1/fsprytwr.pdf>

some of the controlled particulate solids product with fresh lime slurry and re-inject the mixture into the SDA. Finally, the SO₂ concentration at the inlet to the SDA will already have been reduced in the AFBC to a level generally associated with the SDA outlet SO₂ concentration, which will limit the efficiency of the system. Nevertheless, for purposes of this analysis, SDA is considered a technically feasible retrofit control option. It was been assumed that a baghouse, requiring retrofit of the existing particulate matter control system, would be required for proper operation and particulate matter control. SDA control efficiency is typically in the 70% to 90% range.

Control efficiencies assumed achievable for purposes of this analysis are conservative due to being based on operation at high load conditions. The high rate of assumed capture may not be achieved at low load operation. MONTANA-DAKOTA reserves the right to refine the assumptions and impacts to the cost of controls if further study is needed. A full review of the ESP's ability to accept and properly clean the flue gas with changed properties would be needed to determine feasibility and possible costs.

5.1.3.3 Dry Sorbent Injection (DSI)

Dry sorbent injection (DSI) involves the injection of a lime or limestone powder into the exhaust gas stream. The stream is then passed through a baghouse to remove the sorbent and entrained SO₂. The process was developed as a lower cost FGD option because the mixing occurs directly in the exhaust gas stream instead of in a separate tower. Depending on the residence time and gas stream temperature, sorbent injection control efficiency is typically between 50% and 70%. Although a dry sorbent injection system may be technically feasible, it is not practical for use with an AFBC with limestone bed material. The AFBC flue gas already contains excess unreacted lime and fly ash will be reinjected back into the AFBC combustion bed. A dry sorbent injection system would simply add additional unreacted lime to the flue gas. Because the dry sorbent injection system is not practical with an AFBC the system will not be evaluated further.

5.2 Factor 1 – The Cost of Compliance

The pollution control costs are presented on a dollar per ton of pollutant removed calculated according to Equation 2.73 of the Cost Manual and 40 CFR 51, Appendix Y, Section IV, D. The cost effectiveness compares the annualized cost of the technology per ton of pollutant removed and is evaluated on dollar per ton (\$/ton) basis using the annual operating cost (\$/yr) divided by the annual emissions reduction achieved by the control device (ton/yr). Additional details regarding the control equipment cost data and evaluation are noted in the control cost worksheets in Attachment B.

Table 5-2 SO₂ Control Cost Evaluation for Heskett Station Unit 2

Control Technology	Estimated Control Efficiency (%)	Installed Capital Cost (\$)	Annualized Capital Cost (\$/yr)	Pollution Control Cost (\$/ton)
Wet Scrubber	98%	\$80,300,000	\$11,400,000	\$7,700
Spray Dry Absorption	90%	\$70,200,000	\$9,990,000	\$7,300

¹ The NDDH original BART ceiling costs were based on the June 1999 WRAP Annex to Grand Canyon Visibility Transport Report. Scaled to today's dollars, the average cost effectiveness threshold is approximately \$4,460 per ton.

The SO₂ control options evaluated as part of this analysis are considered economically infeasible for implementation at Unit 2 as the average cost effectiveness is not justified on a dollar per ton basis.

5.3 Factor 2 – Time Necessary for Compliance

Under Factor #2, the amount of time needed for full implementation of different control strategies is reviewed. Typically, time for compliance includes the time needed to develop and implement the regulation and/or the time needed to install the necessary emissions control equipment. This analysis does not support the installation of any new retrofit SO₂ emissions controls at Heskett Station Unit 2 and therefore a review of the time necessary for compliance is not applicable.

5.4 Factor 3 – Energy and Non-Air Quality Environmental Impacts

The energy and non-air environmental impacts associated with implementation of the above-identified SO₂ control measures are discussed in the following sections.

5.4.1 Limestone Injection at AFBC

Limestone addition is currently in place at Unit 2 and MONTANA-DAKOTA is implementing best practices to mitigate energy and non-air environmental impacts. The system has been fully operating less than two years and feed rates are still under evaluation for control performance. As discussed with NDDH, when the system was first implemented in 2017, MONTANA-DAKOTA expects increases in the feed of limestone to result in additional handling and disposal issues, diminishing returns for SO₂ control (variable with load levels), and can change bed properties including transfer of energy and fouling.

5.4.2 Wet Lime/Limestone Scrubbing

In addition to the economic impacts of a wet FGD system, there are several collateral environmental impacts associated with its operation. Wet FGD systems generate a calcium sulfate waste by-product that must be properly managed. Historically, solid wastes generated from wet FGD systems have been dewatered and disposed of in landfills. Most new wet FGD systems utilize a forced oxidation system that results in a gypsum by-product that can sometimes be sold into the local gypsum market. If an adequate local gypsum market is not available, the gypsum by-product will require proper disposal. Currently, there is not a viable market in proximity to Heskett Station and usable quantity would be likely limited. A study of disposal at our current facility would be required and, if feasible, additional permitting needed. If not acceptable for sale, disposal costs may be significant and would have to include transport costs. In a northern climate this may be a significant issue.

A wet FGD system will also result in greater particulate matter emissions. Wet FGD systems must be located downstream of the unit's particulate control device therefore, dissolved solids from the wet FGD system will be emitted with the wet FGD moisture plume. In addition, any SO₃ remaining in the flue gas could react with moisture in the wet FGD to generate sulfuric acid mist.

Wet FGD systems also require significantly more water than dry FGD systems or limestone injection systems. Wet FGD control systems typically require approximately 1.0 gpm of water per gross MW output. Additional costs may result from a potential need to increase Heskett Station's existing water rights for

withdrawal of water from the Missouri River for Wet FGD operation. The site faces challenges for space due to rail lines, historical disposal and archeological issues. CCR considerations would need to be evaluated (including location restrictions); state and federal discharge permitting requirements (from the new system) would also be applicable. These would take significant study and time.

5.4.3 Dry Flue Gas Desulfurization (FGD)

Collateral environmental impacts are less significant with dry scrubbing systems. Using a dry FGD system in conjunction with a FBC with limestone injection would require the facility to handle two reactants; limestone for injection in the FBC and pebble lime for use in the dry scrubber. The receipt, storage, management and use of two reactants will result in increased material handling PM emissions.

Lime used in dry FGD systems must be hydrated prior to use, increasing the facility's overall consumption of water. However, water used to hydrate the lime reactant is evaporated in the dry scrubbing system, eliminating the need for additional wastewater treatment and discharge.

5.5 Factor 4 – Remaining Useful Life of the Source

At this time, MONTANA-DAKOTA has assumed that the remaining useful life of the Unit 2 will be longer than the useful life of the emissions control measures evaluated in this analysis. Accordingly, as directed by the July 2006 EPA draft guidance, the useful life of the individual control measures is used to calculate emissions reductions, amortized costs and cost effectiveness on a dollar per ton basis.

5.6 Proposed Controls and Emissions Rates

This analysis does not support the installation of any new retrofit SO₂ emissions controls at Heskett Station Unit 2. The available and potential technically feasible control strategies are economically infeasible and have significant technical and other concerns for operation Heskett Station. Therefore, MONTANA-DAKOTA is proposing to maintain current operational practices consistent with the parameters and limits included as part of the facility's existing Air Pollution Control Title V Permit to Operate (T5-F76001). As discussed throughout this document, the uncertainty around assumed SO₂ emissions control performance, the potential feasibility concerns tied to the operation of the control technologies evaluated and also the required additional cost refinement analysis that would be required prior to implementation, MONTANA-DAKOTA reserves the right to refine this analysis in the future if necessary.

6 Summary and Conclusion

In conclusion, as requested by the NDDH, MONTANA-DAKOTA completed a four-factor analysis evaluating direct emissions of SO₂ and NO_x at Heskett Station Unit 1 and Heskett Station Unit 2. Based on the four- factor evaluation completed in this report, MONTANA-DAKOTA is proposing to maintain current operational practices consistent with the parameters and limits in the R. M. Heskett Station Air Pollution Control Title V Permit to Operate.

All available and potential technically feasible control strategies evaluated are economically infeasible for implementation at Heskett Station. Retrofit control options present significant technical and other operational concerns that would require detailed and extensive study to determine actual feasibility and emissions reduction potential at Unit 1 and Unit 2. Such studies would be costly and only serve to add to the probable highly elevated site-specific costs associated with implementation of retrofit control technologies at Heskett Station and would greatly increase the presented price of emissions reductions on a \$/ton basis.

Further, MONTANA-DAKOTA reserves the right to review and modify the assumptions used in this analysis, primarily concerning site-specific conditions for cost (including capital costs and actual emissions reductions potential/performance) and remaining useful life of the affected sources.

Unit Summary

Unit	Unit 1		Unit 2	
Fuel Type	Lignite		Lignite	
Boiler Type	Normal		Fluidized Bed	
Maximum Hourly Production	25	MWh	75	lb/MMBtu
Maximum Hourly Heat Input Rate	387.63	MMBtu/hr	916.5	MMBtu/hr
Standardized Exhaust Flow Rate	95,133	scfm @ 68° F	235,167	scfm @ 68° F
Exhaust Temperature	420	° F	320	° F
Exhaust Moisture Content	15	%	15	%
Capacity Factor (CF) / Utilization	40	%	63	%
Fuel Sulfur Content	0.91	%		
Expected Annual Hours of Operation	8760	hours	8760	hours
Baseline Emission Rate	5.80	lb/ton lignite	0.46	lb/MMBtu
Hourly Emissions	174	lb/hr	421.59	lb/hr
Annual Emissions	304.8	tons/yr	1,163.3	tons/yr

Control Equipment Costs

Control Technology Name		Low-dust SCR	SNCR	Low-dust SCR	SNCR
Expected Equipment Life (years)		20	20	20	20
NOx Control Efficiency		80%	27%	80%	27%
Ammonia Slip		5	-	5	-
Controlled Emissions (tons/yr)		61.0	223.0	232.7	848.1
Reduction (tons/yr)		243.9	81.8	930.7	315.3
Capital Costs					
Total Capital Investment (TCI = DC + IC)	[1]	\$21,729,380	\$4,178,922	\$41,629,238	\$4,997,248
Operating Costs					
Direct Operating Costs (\$/year)	[2]	\$673,534	\$399,546	\$2,124,053	\$1,270,494
Indirect Operating Costs (\$/year)	[3]	\$1,864,942	\$344,472	\$3,509,034	\$411,536
Total Annual Cost (\$/year)	[4]	\$2,538,476	\$744,018	\$5,633,087	\$1,682,030
Control Cost Effectiveness (\$/ton)		\$10,400	\$9,100	\$6,100	\$5,300

Sending on behalf of Abbie Krebsbach and Jay Skabo

Good afternoon,

I am writing to you because I want you to know about the announcement that Montana-Dakota Utilities made regarding its generation fleet. In case you haven't seen it, the news release is attached. Feel free to share with others in your organization, particularly with air quality, water quality, and waste management permitting areas, where we work closely with you and your staff on permits for our generation facilities discussed below. We will plan to reach out directly to our permitting contacts in the future to discuss our current permitting activities and any permit modifications needed as our plan moves forward.

Montana-Dakota Utilities' plan is to retire three aging coal fired units at two electric generation stations and construct a new simple cycle combustion turbine within the next two to three years.

Montana-Dakota Utilities' mission is to provide safe, reliable and cost-effective service to its customers. Our coal facilities at R.M. Heskett Station and Lewis & Clark Station have done just that for nearly six decades, but we are finding they are no longer cost-competitive.

The decision was made as part of Montana-Dakota's integrated resource plan and will cost-effectively meet the needs of its customers. The company intends to retire the coal unit at Lewis & Clark Station in Sidney, Montana around the end of 2020 and Units 1 & 2 at R.M. Heskett Station near Mandan, North Dakota around the end of 2021. The new natural gas unit will go online in early 2023 at the R.M. Heskett Station. Both stations have existing natural gas fired units that will continue to operate.

If you have questions, please feel free to get back to Abbie Krebsbach at 701-222-7844/701-663-9178 or abbie.krebsbach@mdu.com, me at the contact info further below, or reach out to others on our communications team:

MDU Resources Subsidiary Plans Retirement of Aging Generation Units; New Generation Build

Company Release - 2/19/2019 4:30 PM ET

BISMARCK, N.D., Feb. 19, 2019 /PRNewswire/ -- MDU Resources Group, Inc., (NYSE: MDU) subsidiary Montana-Dakota Utilities announced today that it intends to retire three aging coal-fired electric generation units at two locations within the next two to three years and construct a new simple-cycle natural gas combustion turbine to cost-effectively meet the needs of its customers.

The analysis done while preparing the integrated resource plan (IRP), which the company puts together every two years and files with regulatory commissions, points to the retirement of two aging coal-fired plants and the construction of the natural gas combustion turbine. Low-cost power available on the market, due to low-cost natural gas and increasing wind resources, as well as rising costs to operate these facilities, led to the decision to retire the coal plants. The retirements are expected around the end of 2020 for Lewis & Clark Station in Sidney, Montana, and around the end of 2021 for units 1 and 2 at Heskett Station in Mandan, North Dakota. These dates may be impacted by the company's coal supplier's pending bankruptcy proceeding.

The company has begun the development process to construct an 88-megawatt simple-cycle peaking unit at the Heskett Station site, and anticipates submitting an advance determination of prudence request with the North Dakota Public Service Commission this fall.

The new generation resource was selected as part of Montana-Dakota's IRP. The company believes a second combustion turbine at Heskett will be cost-effective because the site has existing infrastructure and natural gas supply that serves an existing combustion unit that went online in 2014.

"Our main objective is to provide our customers with safe, reliable and low-cost service," said Nicole Kivisto, president and CEO of Montana-Dakota. "The IRP process helps guide us in making decisions to meet those objectives. Heskett and Lewis & Clark have met that objective for many years, but our analysis is showing those units are no longer cost competitive for our customers."

The total cost of building and operating a new simple-cycle combustion turbine, coupled with market purchases, is expected to be about half the total cost of continuing to run the Heskett and Lewis & Clark coal-fired units.

The first coal-fired unit at Heskett went online in 1954 and the second unit in 1963. They combine for 100 MW of power. Lewis & Clark went online in 1958 and provides 44 MW of power. If the company meets the proposed retirement timeline, the plants will range in age from 58-67 years old.

"The plants have served our customers well, providing low-cost energy for many years, operating roughly twice as long as expected when they were constructed in the mid-1950s and early 1960s," Kivisto said. "The age of the plants, low-cost competition on the market, and the ongoing cost to operate the plants all have contributed to the plants being too expensive to operate much longer."

Montana-Dakota has conducted an IRP for many years. The IRP is a way to consider all resource options reasonably available to meet the end-use customer's demand for reliable and cost-effective energy, and provide a road map for Montana-Dakota's future resources. The IRP process includes four areas: Load forecasting, demand-side analysis, supply side analysis, and integration and risk analysis.

Montana-Dakota's customers also have benefited from low-cost energy available on the MISO market and the long-range forecast calls for similar savings in future years. MISO, the Midcontinent Independent System Operator, is a not-for-profit member-based organization that ensures reliable, least-cost delivery of electricity across all or parts of 15 U.S. states and one Canadian province. In cooperation with stakeholders, MISO manages approximately 65,000 miles of high-voltage transmission and 200,000 MW of power-generating resources across its footprint.

Montana-Dakota currently employs 77 people between the two coal stations. Once the units are no longer in operation, Montana-Dakota estimates approximately 10 employees will be needed to operate the two natural gas-fired combustion turbine units at Heskett and the two natural gas-fired reciprocating internal combustion engines at Lewis & Clark. The plan is in place intended to maintain staff until the plant retirements, and the company will offer training for employees who wish to fill open positions in other areas of the company.

About MDU Resources

MDU Resources Group, Inc., a member of the S&P MidCap 400 index and the S&P High-Yield Dividend Aristocrats index, is Building a Strong America® by providing essential products and services through its regulated energy delivery and construction materials and services businesses. For more information about MDU Resources, see the company website at www.mdu.com or contact the Investor Relations Department at investor@mduresources.com.

About Montana-Dakota Utilities

Montana-Dakota Utilities Co., a subsidiary of MDU Resources, distributes natural gas and generates, transmits and distributes electricity and provides related services in the northern Great Plains. The company serves approximately 143,000 electric customers and 275,000 natural gas customers in 262 communities in North Dakota, South Dakota, Montana and Wyoming.

Forward-Looking Statement

The information in this release includes certain forward-looking statements within the meaning of Section 21E of the Securities Exchange Act of 1934, as amended. The forward-looking statements contained in this release, including statements made by the president and CEO of Montana-Dakota and statements relating to plans and expectations regarding the construction of a simple cycle combustion turbine, retirement of existing generating stations, related costs and other benefits, and Montana-Dakota's integrated resource plan are expressed in good faith and are believed by the company to have a reasonable basis. Nonetheless, actual results may differ materially from the projected results expressed in the forward-looking statements. For a discussion of important factors that could cause actual results to differ materially from those expressed in the forward-looking statements, refer to Item 1A-Risk Factors in MDU Resources' most recent Form 10-Q and 10-K.

B.7 – Little Knife Gas Plant
B.7.a – Department Request

May 18, 2018

FILE

Mr. Derek Enderud
Petro-Hunt, LLC
390 - 119th Avenue SW
Killdeer, ND 58640

Re: Regional Haze
Second Planning Period

Dear Mr. Enderud:

The Department of Health (Department) has begun work on the second planning period (Round 2) State Implementation Plan (SIP) for regional haze. In Round 1 of the regional planning process, the emphasis was on Best Available Retrofit Technology (BART) and making reasonable progress towards the national visibility goal. In Round 2, there are no BART requirements; therefore, we will focus on making reasonable progress. The reasonable progress analysis will be made using the four factors in Section 169A(g)(1) of the Clean Air Act:

The four factors are:

1. The cost of compliance
2. The time necessary to achieve compliance
3. The energy and non-air quality environmental impact of compliance; and
4. The remaining useful life of any existing source subject to such requirements

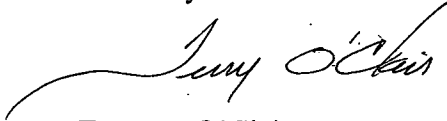

Guidance provided by the U.S. Environmental Protection Agency (Draft Guidance on Progress Tracking Metrics, Long Term Strategies, Reasonable Progress Goals and Other Requirements for Regional Haze State Implementation Plans for the Second Implementation Period at https://www.epa.gov/sites/production/files/2016-07/documents/draft_regional_haze_guidance_july_2016.pdf) indicates the Department must address 80% of the visibility impairment caused by in-state sources. Data from the IMPROVE monitoring sites at Theodore Roosevelt National Park (TRNP) and Lostwood Wilderness Area (LWA) indicate that sulfates and nitrates continue to be the largest contributors to visibility impairment in these areas. The primary precursors of sulfates and nitrates are emissions of sulfur dioxide (SO₂) and nitrogen oxides (NO_x).

The Little Knife Gas Plant emits a significant amount of SO₂ and is located close to a Class I area. Therefore, the Department requests that you prepare a "four factors" analysis for the plant. The analysis should be prepared using the draft EPA guidance noted above. The analysis should address emissions from the amine sweetening unit (Emission Unit A-1) and the flare (Emission Unit F-1).

Preparation of the Round 2 Regional Haze SIP will require extensive planning and review of emission sources in North Dakota. The Department will be working with the Western Regional Air Partnership (WRAP) to prepare the SIP. WRAP will be conducting air quality modeling of potential regional emissions reductions in early 2019. The Department asks that your "four factors" analysis be submitted by January 31, 2019.

If you have any questions, please contact David Stroh of my staff at (701)328-5188.

Sincerely,

A handwritten signature in cursive script, reading "Terry O'Clair".

Terry L. O'Clair
Director
Division of Air Quality

David,

Attached is a summary of the four factor analysis requirements relating to the second planning period of the State Implementation Plan (SIP) for Regional Haze.

The summary includes the projected reduction of sulfur dioxide with potential additional controls. The attachments include the estimated cost of the controls along with the estimated energy and non-air environmental impacts.

Thank you for proving me with the additional information you sent, as well as explaining the history of these studies. It was a great help. If you have additional questions please give me a call.

Petro Hunt Little Knife Gas Plant
State Implementation Plan (SIP) for Regional Haze Round 2
Four Factor Analysis

Table 1: Outlines the emission control measures that have already been applied to these sources, the baseline levels of emissions with these current controls, and potential additional control measures that could be adopted to further reduce emissions. The table also gives the estimated control efficiency and annual emission reduction for each potential future control measure.

(1) Existing Control Measures and Potential Additional Control Options for Natural Gas Processing Operations							
Source	Pollutant	Existing Controls	Baseline Emissions (tons/yr.)	Potential additional control measures	Estimated Control efficiency (%)	Potential emission reduction (tons/yr.)	References
Sulfur recovery unit, 2-stage, 2-bed, 120 long tons/day sulfur	Sulfur Dioxide	2- stage unit with cold bed adsorption, > 88 % efficiency	432	Replacement of catalyst in Reactors 1 & 2	90%	39.42	Catalyst Replacement in Reactors 1 & 2 Attachment
Sulfur recovery unit, 2-stage, 2-bed, 120 long tons/day sulfur	Sulfur Dioxide	2- stage unit with cold bed adsorption, > 88 % efficiency	432	Acid Gas Injection Well	100%	320	Acid Gas Injection Well and Catalyst Replacement Reactor 1 & 2 Attachments

Table 2 Factor 1: Provides cost estimates for the emission control options which have been identified for the North Dakota gas processing facilities. For each option, the table gives an estimate of the capital cost to install the necessary equipment, and the total annual cost of control, including the amortized cost associated with the capital equipment cost. The table also shows the estimated cost effectiveness for each control measure, in terms of the cost per ton of emission reduction.

Factor 2: Once the regional haze control strategy is formulated for North Dakota, up to 2 years will be needed for the state to develop the necessary rules to implement the strategy. We have estimated that sources may then require up to a year to procure the necessary capital to purchase control equipment. The ICAC has estimated that approximately 13 months is required to design, fabricate, and install SCR or SNCR technology for NOX control. However, state regulators' experience indicates that closer to 18 months is required to install this technology. In the Clean Air Interstate Rule (CAIR) analysis, EPA estimated that approximately 30 months is required to design, build, and install SO2 scrubbing technology for a single emission source. The analysis also estimated that up to an additional 12 months may be required for staging the installation process if multiple sources are to be controlled at a single facility. Based on these figures, the total time required achieve emission reductions for the Petro Hunt facility would be up to 6½ years. This includes 2 years for regulatory development, 1 year for capital acquisition, and 2½ years for designing, building and installing. This estimate includes the same components as the estimate for Petro Hunt, with an additional year for staging the installation of controls for multiple emission sources.

(2) Estimated Costs of Control for Natural Gas Processing Operations - Factor 1								
Source	Control Option	Pollutant	Estimated control efficiency (%)	Potential emission reduction (tons/yr.)	Estimated capital cost (\$1000)	Estimated annual cost (\$1000/yr.)	Cost effectiveness (\$/ton)	References
Sulfur recovery unit, 2-stage, 2-bed, 120 long tons/day sulfur	Replacement of catalyst in Reactors 1 & 2	Sulfur Dioxide	90%	39.42	103.95	10.39	2,636.99	Catalyst Replacement in Reactors 1 & 2 (attachment)
Amine Treating Unit	Acid Gas Injection Well	Hydrogen Sulfide and Carbon Dioxide	100%	320	4,229.58	624.71	13,665.53	Acid Gas Injection Well, Estimated Cost of Control, & Catalyst Replacement in Reactors 1 & 2 Attachments

Table 3 Factor 3: Shows the estimated energy and non-air pollution impacts of control measures for sources at the Petro Hunt facility. The table shows the additional fuel, electricity, and steam requirements resulting required to operate the control equipment; and the additional solid waste would be produced. CO2 emissions associated with the generation of the additional electricity and steam are also estimated in the table.

(3) Estimated Energy and Non-Air Environmental Impacts of Potential Control Measures for Natural Gas Processing

Energy and non-air pollution impacts (per ton of emission reduced)

Source Type	Control Technology	Pollutant Controlled	Potential emission reduction (ton/yr.)	Additional Fuel Req. (%)	Electricity Req. (kw-hr)	Steam Req. (tons steam)	Solid waste Produced (tons)	Additional CO2 emitted (tons)
Sulfur recovery unit, 2-stage, 2-bed, 120 long tons/day sulfur	Activated Alumina Promoted Claus Catalyst	Sulfur Dioxide	39.42	0	0	0	0	0
Amine Treating Unit	Downhole Formation Injection	Hydrogen Sulfide and Carbon Dioxide	320	0	3,504,000	0	0	0

Factor 4: It is not possible to compute the remaining service lifetimes of these sources since emission sources at industrial facilities are often refurbished. The remaining lifetimes of the SRUs and compressors are expected to be longer than 15 year figure which has been used to amortize the capital costs of add-on emission controls or equipment modifications to reduce emissions. If the remaining life of an emission source is less than the projected lifetime of a pollution control device, then the capital cost of the control device would have to be amortized over a shorter period of time, corresponding to the remaining lifetime of the emission source. This would cause an increase in the amortized capital cost of the pollution control option, and a corresponding increase in the total annual cost of control.

Little Knife Plant SO₂ Reduction Options

Option #1

Catalyst Replacement in Reactors

Replacement of catalyst in CBA reactor bed #1 and #2

This change would take efficiency levels from 88% to 90% and reduce hourly SO₂ emissions by approximately 9 pounds per hour.

COST

\$ 29,481.40	Catalyst reactor #1
\$ 17,339.50	Catalyst reactor #2
\$ 25,000.00	Labor
\$ 20,000.00	Catalyst removal
\$ 1,000.00	Catalyst disposal 30 tons
\$ 750.00	Disposal transportation
\$ 3,360.00	Sulfur production lost
	Residue flared for complete conversion of H ₂ S to SO ₂ in process flare =2.35 times acid gas to flare
\$ 2,021.00	430 x 2.35= 1010.5 MCF/D 1010.5 x \$2.00= \$2,021.00
\$ 12,600.00	Crane
\$ 111,551.90	Total

Time to complete

14 days	Shutdown unit, cool, disassemble, enter reactor, remove catalyst, replace catalyst, warmup unit, restart
---------	--

ENVIRONMENTAL IMPACT

788 pounds of H ₂ S to flare per hour
1100 MCF residue gas flared per day
1000 MCF residue gas burned to reheat unit for restart
9 pounds of SO ₂ less per hour 73 lb/hr @ 88.63% efficiency versus 64 lb/hr @ 90% efficiency
9 x 8760 hrs. / 2000 lbs = 39.42 tons.

USEFUL LIFE OF EQUIPMENT

7-10 years	After this time efficiency will be back to 88% levels

NON-OPERATOR									
Approval of this AFE constitutes NON-OPERATOR'S approval of and commitment to pay all costs incurred in connection with the performance of the operations proposed herein and agreement to bear all risks and liabilities associated with such operations as to NON-OPERATOR'S interest as specified herein and as required by any applicable operating agreement. It is specifically recognized that the costs indicated in this AFE are estimates only and the actual costs may vary from the estimate.									
APPROVED BY: _____						DATE: _____			
This AFE includes Operator's Extra Expense (Blowout) insurance which provides coverage during drilling and completion operations. If you do not desire to have Operator provide the coverage for you, please indicate so in the space below and enclose a copy of your Insurance Certificate outlining your coverage. NO RESPONSE shall result in a conclusive presumption of acceptance.									
NOT APPROVED: _____						DATE: _____

Estimated Cost Of Control

Table 2

Estimated Capitol Cost:

Injection Well: \$2,539,400.00

Acid Gas Compressor: \$1,670,000.00

Compressor piping and associated equipment, installation and labor: \$20,183.71

Total: \$4,229,583.71

Estimated Annual Cost:

Maintaining the compressor with pistons, rods, rings, rider bands, packings, valves, oil etc. would be approximately \$15,000.00 / year.

Electrical Cost: \$128,385.00

Injection Well, Acid Gas Compressor, & Piping amortization cost over seven years: \$4,229,583.71

Total Cost: \$4,372,968.71 / 7 = \$624,709.82

Cost Effectiveness \$/ton:

\$4,372,968.71 / 320 tons = \$13,665.53

Table 3

Electricity Required (kw-hr)

Operating a 2400-volt, 500 HP motor, drawing 107 amps, using 400 KWH cost \$351.74 / day.

$351.74 \times 365 = \$128,385.00$ / year.

400 kwh x 8760 = 3,504,000

Acid Gas Compressor Cost

Good morning Gary / Ryan,

I had a look at some acid gas injection compressor packages Bidell has recently completed and have the following summary;

Typical design conditions

Suction pressure range – 4 – 9 psig

Discharge pressure range – 2000 – 3200 psig with a couple at 1000 psig and one at 200 psig

Flow rates -0.4 – 1.32 mmscfd

Horsepower required – 100 – 450 hp

Cost - \$800,000.0 - \$1,670,000.00 c/w with full installed arctic building

I had a look at your conditions and provided the attached performance summary to give you an idea of the compressor size and horsepower required to inject 0.4 mmscfd at 3 psig suction and 900 psig discharge pressure. The frame that fits well is the Ariel JG-4 with 4 stages of compression and driven by ~ 150 hp electric motor. The flow rate is as follows;

Target - 0.4 mmscfd @973 rpm

Low flow – 0.308 mmscfd @ 750 rpm

High flow – 0.576 mmscfd @ 1400 rpm

I would estimate this package would run in the \$900,000.00 – \$1,100,000.00 range (to give you a cost idea) and would estimate delivery lead times to be about 30 – 32 weeks. I have attached a number of pictures to show some AGI packages during fabrication and after completion.. The package would come with its own control panel mounted in the package that could be connected to the plant PLC and a full arctic style building with heaters (which can be deleted if you plan to put this package into an existing building)

Please review the attached pictures and performance summary and let me know if you have any additional questions... if you would like, I could have a proposal generated and submitted to you for consideration in the next couple of weeks (this would provide a better idea of the full scope of supply). As I indicated in our meeting, Bidell has placed about 70,000 hp of compression on the ground in ND in the last 12 – 18 months, if you would like some local references or would like to go and look at one of the Bidell supplied packages, let me know and I will arrange a site visit...

I look forward to your initial comments...

Thanks again for your time...

Mr. Terry O'Clair

RE: Regional Haze
Second Planning Period

This letter is regarding the second period State Implementation Plan (SIP) for regional haze. In the past forty years the Little Knife Gas Plant has always strived to achieve the very best it can to minimize emission sources and increase the national visibility utilizing the Best Available Retrofit Technology (BART) as well as making reasonable progress through ongoing process analysis.

The reports sent to the State of North Dakota Health Department are not only a requirement but an indication of our efforts to reduce emissions and improve air quality. Reports are sent on an Annual, Semi-annual and Quarterly basis documenting our emission sources, the quantity of pollutants and reliability of our emission monitoring equipment.

Though the Little Knife Plant emits a significant amount of SO₂ our records show the sulfur plant operates at 32.3% below the established hourly threshold set by the State with a recovery rate between 92 -94%. In addition to monitoring sulfur dioxide, we also monitor for GHG and VOC detection.

With the discovery of the Bakken formation, our inlet gas to the amine sweetening unit containing Hydrogen Sulfide has reduced significantly, therefore a significant reduction in sulfur dioxide. There has never been an exceedance in our process flare and only five one-hour exceedances from the incinerator on the Sulfur Plant in the past ten years.

Petro Hunt will continue to communicate with the appropriate agencies, as well as continue making reasonable progress to improve air quality. If the volume of Hydrogen Sulfide continues to decline, Petro Hunt will research the possibility of Acid Gas injection.

We are aware of the Plant's location to the Theodore Roosevelt National Park. It has always been our goal to continually improve operations to minimize the amount of sulfur dioxide, nitrous oxides, particulates, and organic compounds along with any other source of emissions to protect the environment and improve visibility impairment.

Sincerely,
Gary Kohler

Re: Regional Haze
Second Planning Period

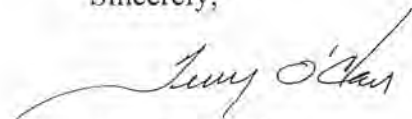

Dear Mr. Kohler:

We have reviewed your November 29, 2018 email response to the Department's request for a four factors analysis for the Little Knife Gas Plant. Your response did not provide the requested analysis and does not adequately address the requirements of the Regional Haze Program. An appropriate analysis must address options for reducing sulfur dioxide at the plant including acid gas injection. The analysis must provide a cost analysis of the various options, the time necessary to achieve the reductions, the energy and non-air quality environmental impacts of the options and you may consider the remaining useful life of the equipment. The required analysis is very technical and may require Petro-Hunt, LLC to retain the services of an engineering consultant. Based on your analysis and our own, the Department will require appropriate actions to aid in achieving reasonable progress toward the national visibility goal.

Under NDCC 23-25, the Department has the authority to require this analysis. We suggest a meeting be arranged between Petro-Hunt and the Department to discuss the analysis. If you have a consultant, they are free to attend the meeting. We will be in contact you to set up this meeting.

If you have any questions, please feel free to contact David Stroh of my staff at (701) 328-5188.

Sincerely,

Terry L. O'Clair
Director
Division of Air Quality

Re: Regional Haze
Second Planning Period

Dear Mr. St. Clair:

The Department of Health (Department) has begun work on the second planning period (Round 2) State Implementation Plan (SIP) for regional haze. In Round 1 of the regional planning process, the emphasis was on Best Available Retrofit Technology (BART) and making reasonable progress towards the national visibility goal. In Round 2, there are no BART requirements; therefore, we will focus on making reasonable progress. The reasonable progress analysis will be made using the four factors in Section 169A(g)(1) of the Clean Air Act:

The four factors are:

1. The cost of compliance
2. The time necessary to achieve compliance
3. The energy and non-air quality environmental impact of compliance; and
4. The remaining useful life of any existing source subject to such requirements

Guidance provided by the U.S. Environmental Protection Agency (Draft Guidance on Progress Tracking Metrics, Long Term Strategies, Reasonable Progress Goals and Other Requirements for Regional Haze State Implementation Plans for the Second Implementation Period at https://www.epa.gov/sites/production/files/2016-07/documents/draft_regional_haze_guidance_july_2016.pdf) indicates the Department must address 80% of the visibility impairment caused by in-state sources. Data from the IMPROVE monitoring sites at Theodore Roosevelt National Park (TRNP) and Lostwood Wilderness Area (LWA) indicate that sulfates and nitrates continue to be the largest contributors to visibility impairment in these areas. The primary precursors of sulfates and nitrates are emissions of sulfur dioxide (SO₂) and nitrogen oxides (NO_x).

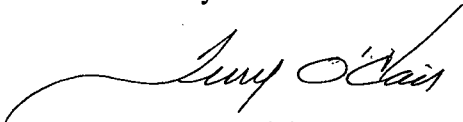

The Tioga Gas Plant has been identified as a significant source of both SO₂ and NO_x. Therefore, the Department requests that you prepare a "four factors" analysis for the Tioga Gas Plant. The analysis should be prepared using the draft EPA guidance noted above. The following units should be addressed in the analysis:

1. Amine Gas Sweetening Unit (Emission Unit S302)
2. Clark Compressor Engines (Emission Units C1A – C1G)
3. Flares (Emission Units S101 and S102)

Preparation of the Round 2 Regional Haze SIP will require extensive planning and review of emission sources in North Dakota. The Department will be working with the Western Regional Air Partnership (WRAP) to prepare the SIP. WRAP will be conducting air quality modeling of potential regional emissions reductions in early 2019. The Department asks that your “four factors” analysis be submitted by January 31, 2019.

If you have any questions, please contact David Stroh of my staff at (701)328-5188.

Sincerely,

Terry L. O'Clair
Director
Division of Air Quality

Bismarck, North Dakota 58501-1947

Re: REGIONAL HAZE
SECOND PLANNING PERIOD
TIOGA GAS PLANT

Dear Mr. O'Clair:

As requested in your letter to me dated May 18, 2018 concerning the referenced subject matter, please find enclosed the "Four Factors Analysis" report as it pertains to emissions of sulfur dioxide (SO₂) and nitrogen oxides (NO_x) at the Hess Tioga Gas Plant, located in Tioga, North Dakota.

The report was developed with consideration of the four factors in Section 169A(g)(1) of the Clean Air Act, using specific guidance provided by the U.S. Environmental Protection Agency (Draft Guidance on Progress Tracking Metrics, Long Term Strategies, Reasonable Progress Goals and Other Requirements for Regional Haze State Implementation Plans for the Second Implementation Period).

The four factors are:

1. The cost of compliance
2. The time necessary to achieve compliance
3. The energy and non-air quality environmental impact of compliance; and
4. The remaining useful life of any existing source subject to such requirements

As requested, the following units at the Tioga Gas Plant were addressed due to their significant potential emissions of SO₂ and NO_x (precursors to sulfates that may lead to visibility impairment):

1. Amine Gas Sweetening Unit (Emission Unit S-302)
2. Clark Compressor Engines (Emission Units C1A – C1G)
3. Flares (Emission Units S-101 and S-102)

If you should have any questions regarding this information, please contact me at (713) 496-5031.

Sincerely,

A handwritten signature in blue ink, appearing to read "Tony St. Clair".

Houston, Texas 77010**

December 20, 2018

EXECUTIVE SUMMARY

Bison Engineering, Inc. was retained by Hess Corporation to prepare a 4-Factor analysis for specific units located at their Tioga Gas Plant located at Tioga, ND. The 4-Factor analysis was requested by North Dakota's Environmental Health Section, Division of Air Quality in a letter dated May 18, 2018.

The analysis itself relates to "Round 2" of development of a State Implementation Plan (SIP) to address Regional Haze. Regional haze requirements and goals are found in Section 169A of the Federal Clean Air Act and codified in 40 CFR 51.308. The purpose of the 4-Factor analysis is, to determine if there are control options at Hess to reduce emissions, that could be used to attain "reasonable progress" toward the state's visibility goals.

The 4-Factor analysis was conducted on three source groups at the Hess facility: amine sweetening unit, compressor engines and flares. The results of the analysis have indicated that additional controls on these units are not necessary to make reasonable progress due to costs and other considerations. It is concluded that these sources do not qualify for additional emission controls or limitations based on the 4-Factor analysis.

APPENDIX A: COST ANALYSIS	
---------------------------	--

1.0 INTRODUCTION

With the 1977 amendments to the Federal Clean Air Act (42 USC 7401 *et. seq.*) Congress declared as a national goal “... *the prevention of any future, and the remedying of any existing, impairment of visibility in mandatory class I Federal areas which impairment results from manmade air pollution.*” [42 USC 7491(a)(1)]. That goal, plans and requirements were eventually codified in the Code of Federal Regulations primarily in 40 CFR 51.308. (The entire visibility program is found in 40 CFR 51.300 → 309). Individual states are required to establish “reasonable progress goals” [40 CFR 51.308(d)(1)] in order to “attain natural visibility conditions” by the year 2064 [§308(d)(1)(i)(B)].

The state of North Dakota has met the first round of those obligations with the establishment of Best Available Retrofit Technologies (BART) for various sources. A second round of obligations is now under development. The Regional Haze Rule (RHR) requires an additional step toward ‘reasonable progress’ in meeting the national goal.¹ The RHR identifies four factors which should be considered in evaluating potential emission control measures to make reasonable progress toward the visibility goal. These are as follows:

- Factor 1. Cost of compliance
- Factor 2. Time necessary for compliance
- Factor 3. Energy and non-air quality environmental impacts of compliance
- Factor 4. Remaining useful life of any existing source subject to such requirements

These four factors are collectively known as the 4-Factor analysis.

To implement the requirement, the North Dakota Department of Health (NDDH) submitted a letter to Hess dated May 18, 2018. The letter noted that NDDH needed to address 80% of the visibility impairment caused by ND sources.² According to NDDH, visibility data from the IMPROVE ambient monitoring sites at Theodore Roosevelt National Park (TRNP) and Lostwood Wilderness Areas indicate that sulfates and nitrates (via SO₂ and NO_x; respectively) are the largest contributors to visibility impairment.³

In order to determine which ‘nearby’ sources should be subject to a 4-Factor analysis, NDDH conducted a Q/d (emissions/distance) analysis of SO₂ and NO_x for industrial

¹ The national goal is to attain natural visibility conditions in mandatory Class I areas by the year 2064 [40 CFR 51.308(d)(1)(i)(B)].

² According to NDDH this value is derived from information contained in EPA’s Draft Guidance on Progress Tracking Metrics, Long Term Strategies found at: https://www.epa.gov/sites/production/files/2016-07/documents/draft_regional_haze_guidance_July_2016.pdf.

³ Hess does not necessarily agree or disagree with this assessment at this time. Hess is providing the information in this document as requested by NDDH.

sources within the state. That analysis has indicated that there are three Hess sources (or source groups) that warrant the analysis according to NDDH. These sources are:

1. Amine Gas Sweetening Unit (Emission Unit S302)
2. Clark Compressor Engines (Emission Units CIA- CIG)
3. Flares (Emission Units S101 and S102)

Therefore, NDDH has requested HESS conduct a 4-Factor analysis for these units to assess potential reductions in SO₂ and NO_x emissions. The May 18 letter requested the analysis be completed no later than January 31, 2019.

Although NDDH requested an analysis of both SO₂ and NO_x for all three source groups, subsequent analysis prompted a small change to the request. Based on correspondence between Hess and NDDH⁴, it was agreed no robust analysis was necessary for SO₂ for the Clark Compressor Engines. Since these engines are fired with pipeline quality natural gas, there are no substantive SO₂ emissions from this source category. A similar conclusion was reached with respect to NO_x emissions from the Amine Gas Sweetening unit. At the time of the email correspondence it was believed that NO_x emissions from these units are low, so there would be no real visibility benefit by attempting to add additional NO_x controls. However, subsequent review found a published emission factor for these units. The published factor indicated a low emission rate, as suspected. However, since an emission rate was available, it was decided to proceed with an analysis even though the reduction in NO_x, should additional controls be added, would not yield any measurable improvement in visibility.

Based on the discussion above and agreement with NDDH⁵, no formal SO₂ analysis was conducted for the compressor engines. For completeness, an NO_x review was conducted for the Amine Sweetening Unit albeit with low actual emission rates.

The remainder of this document outlines the approach used to conduct the 4-Factor analyses along with a detailed analysis for each group.

⁴ Email to David Stroh from Tony St Clair (9/14/18) and associated reply (9/17/18)

⁵ Ibid.

2.0 APPROACH AND METHODOLOGY

The Tioga Gas Plant, the subject of this 4-Factor analysis, is located at 10340 68th Street NW in Tioga, North Dakota. The location is W½, NE¼ S26, T157N, R95W in Williams County. The plant is used to process natural gas from well sites for sale to customers.

The May 18, 2018 letter from NDDH provided some recommendations for conducting the 4-Factor analysis. That information was supplemented based on an email from David Stroh (NDDH) to Tony St. Clair (Hess) which provided further discussion and recommendations (June 2018). The matter was again discussed in a phone conference call between the staff of NDDH, Hess, and Bison Engineering on June 20.

The most complicated or in-depth analysis of the four is Factor #1: Cost of Compliance. The NDDH email and phone conversation suggested this analysis should follow, in general terms, the methods conducted for a Best Available Control Technology (BACT) review. The agency made clear that this is not, in and of itself, a pure BACT analysis; only that the typical steps might be followed.

In addition to the direct contact with NDDH described above, EPA has provided draft guidance (EPA Draft Guidance) of its own for the entire Round 2 procedures including suggested methods for assessing the Cost of Compliance as well as the other 3 factors.⁶ That guidance was published in July 2016 as a draft. We are not aware that the Draft Guidance has been finalized. Nonetheless, since this was the most up-to-date EPA guidelines available, that document was consulted for conducting this 4-Factor analysis.

In general, the cost analysis uses the general approach for BACT, but is modified by the EPA Draft Guidance⁷ and EPA's Control Cost manual⁸. The approach used in this analysis follows these recommendations and guidelines as much as practicable. The other 3 factors employed suggestions from the EPA Draft Guidance as much as reasonable or available data might have allowed.

⁶ "Draft Guidance on Progress Tracking Metrics, Long-term Strategies, Reasonable Progress Goals and Other Requirements for Regional Haze State Implementation Plans for the Second Implementation Period," EPA, EPA-457/P-16-001, July 2016.

3.0 4-FACTOR ANALYSIS

A 4-Factor analysis was completed for the three Hess sources/source groups selected by the NDDH Q/d analysis. The following outlines the analysis for each source using primarily the direction of the EPA Draft Guidance⁹ and the WRAP 2009 4-Factor analysis¹⁰.

The initial step in the 4-Factor analyses was to identify possible additional control options for each source or source group. The options chosen include control techniques addressed in guidelines published by the EPA, emission control cost models such as AirControlNET, Best Available Retrofit Technology (BART) analyses, White Papers prepared by the Midwest Regional Planning Organization (MRPO), and National Association of Clean Air Agencies (NACAA).

The options for each source/source category are summarized in the Table 1.

Table 1: Additional Control Options by Source Group

Source	Emission Unit ID	Pollutant	Existing Controls	Control Efficiency (Existing)	Potential Additional Control Measures
Amine Gas Sweetening Unit (Sulfur Recovery Unit)	S302	SO ₂	2-Stage Claus + CBA (cold bed adsorption) + tail gas incinerator	>98%	Tail-Gas Scrubbing Treatment Unit (Oxidation or Reduction Options)
		_____		_____	Traditional Flue Gas Desulfurization (FGD)
		NO ₂		---	SCR
Clark Compressor Engines (Natural gas pipeline compressor engines)	C1A through C1G	NO ₂	Lean Burn Engines	---	Low Emission Combustion (LEC) - Turbocharge - Air-to-fuel - Ignition timing - Etc.
					SCR
					Electric Motor Replacement
Acid/Wet Gas Flare And High Pressure Flare	S101 and S102	SO ₂ NO ₂	None	---	None

Amine Gas Sweetening Unit (SO₂)

The amine gas sweetening unit at the Hess Tioga Gas Plant facility controls sulfur dioxide (SO₂) emissions via two steps. The first is a 2-stage Claus process. This process converts hydrogen sulfide (H₂S) and SO₂ into elemental sulfur (S) via the 'Claus' reaction. The general reaction is: $\text{H}_2\text{S} + \text{SO}_2 \leftrightarrow \text{S} + \text{H}_2\text{O}$ (unbalanced). To drive the reaction toward completion, the facility further utilizes Cold Bed Adsorption (CBA) which allows this reversible reaction to proceed further. The CBA was installed in 1991. All-in-all the unit collectively reduces SO₂ emissions by 98+%.

Tail-Gas Scrubbing Treatment

The most common control measures that may be applied to a typical refinery-based Claus facility (with or without CBA) are generally categorized as Tail-Gas Scrubbing Treatment unit (TGST). These units use either an oxidation or a reduction measure to continue to convert the underlying sulfur gas to elemental sulfur. The other common measure of removing sulfur dioxide from a gas stream is a traditional Flue Gas Desulfurization (FGD) unit that is more typically used at coal or oil-fired electrical generating units.

The TGST control would add an additional scrubbing process to the Claus exhaust stream prior to the tail-gas incinerator. The processes typically convert the Claus exhaust to either H₂S (reducing process) or SO₂ (oxidizing process). In either case, the 'newly created' H₂S or SO₂ is then returned in some fashion to the Claus or CBA portion of the facility to extend the elemental sulfur recovery.

There are a number of processes that achieve this aim. Regarding the oxidation method, the exhaust stream from the CBA would oxidize the various sulfur compounds (S, H₂S, COS ...) to sulfur dioxide. The sulfur dioxide is then concentrated and used in the Claus/CBA process itself. There are several varieties of processes within the oxidation method. They include the Stauffer, Wellman-Lord and Aquaclaus. Only the Wellman-Lord process has been applied successfully in any US refinery.¹¹

The reduction process, however, is the more typical refinery-based method of additional sulfur dioxide control. This process converts the sulfur gases from the Claus (or CBA) to H₂S. The H₂S is then sent to a scrubber for removal prior to a tail-gas incinerator. The H₂S scrubber typically uses an amine process (similar to the amine unit itself) to capture the H₂S and then recycles this captured H₂S (now in a concentrated stream) back to the Claus plant.

Four common systems utilizing the reduction control method are the Beavon, Beavon MDEA, Shell Claus Off-gas Treatment (SCOT), and ARCO. The most common among these is the SCOT unit.

¹¹ AP-42, Section 8.13, 1995, p 8.13-4.

There are other units designed for refinery-like facilities to remove additional sulfur from the CBA stream. These include the Superclaus¹², Euroclaus¹³ and others. For purposes of this analysis, however, it was decided not to attempt a specific cost analysis for each process. It was reasonable to pick one of the methods described above and conduct an analysis on that process.¹⁴ It seems more than reasonable to presume that the cost of one of these processes is within range of what might be expected for any single process. Additionally, cost estimates for these processes is not readily available. For example, there is no published data for the Superclaus or Euroclaus. Additionally, cost data is very sketchy for many of the other units as well.

It was decided to use the SCOT process as a surrogate for any and all of the TGST discussed above. While there is not a plethora of cost data for this unit, it has the most, albeit limited, available data. In addition, the removal efficiency among all the units, including the SCOT, are similar. They all range in overall sulfur removal from about 98% to 99%+. Should the results of the SCOT (as a representative of TGST) prove favorable, then a more detailed review of some of the options would have been useful.

The SCOT system consists of a reduction process and an alkanol amine absorption process. The process starts by converting (reducing) sulfur compounds to H₂S via a catalyst, heat, and reducing agent (H₂, CO, ...). The captured H₂S is sent back to the Claus feed. The remaining gas is sent to the tail-gas incinerator.

Flue Gas Desulfurization (FGD)

The second class of sulfur dioxide scrubbing for consideration is the traditional Flue Gas Desulfurization (FGD) unit. As noted earlier, this is the typical sulfur dioxide control system found in most coal and oil-fired electrical generation systems across the U.S. The FGD unit may be configured as a wet, semi-dry, or dry scrubber system. In all cases an alkaline compound (typically CaCO₃ or CaO) is used to react with SO₂ (an acidic gas) to form a compound such as CaSO₃. The CaSO₃ (and its related compounds) are then removed via a particulate control device such as a baghouse. EPA estimates FGD units' reduction emissions in the range of 50% to 98% where typically wet scrubbers achieve the highest control potential.¹⁵

While this may seem attractive, the FGD scrubbers have significant *a priori* disadvantages for this application. Among them include:

¹² Information regarding the Superclaus may be found here:
http://www.digitalrefining.com/literature/1000817,Sulphur_Recovery_SUPERCLAUS___Process.html#.W-TGFPZFzDI

¹³ Information regarding the Euroclaus may be found here.
http://www.digitalrefining.com/literature/1000580,Sulfur_recovery___EUROCLAUS___process.html#.W-TFnfZFzDI

¹⁴ This approach is discussed in the EPA Guidance. (See footnote 9).

¹⁵ EPA Air Pollution Control Technology Fact Sheet – Flue Gas Desulfurization:
<https://www3.epa.gov/ttnecat1/dir1/ffdg.pdf> *

- (a) In order to operate an FGD system, it is necessary to have a significant amount of (solid) material handling equipment on site. This would also include a large surface area to store, move and otherwise handle the reagent and spent-reagent material. This equipment and space might typically be available and designed in an FGD installation such as a coal-fired electrical generation station which handles materials (coal, e.g.) on routine basis. For this gas processing facility, however, none of the required space nor handling equipment is readily available. This would require a significant redesign of the facility in both layout and surface disturbance.
- (b) FGD systems require a particulate control device to remove the alkaline scrubbing agent (CaCO_3 , Ca(OH)_2 , CaO , ...). In a typical power plant facility, a control device to remove particulate would be required regardless of the SO_2 scrubber. For this application, however, no such device is installed nor necessary as particulate emissions from amine sweetening units (with Claus sulfur recovery) is nearly non-existent.

Thus, in order to install and operate an FGD for this facility, not only is an FGD itself necessary, but a complete particulate removal system will be required as well (typically a fabric filter). Thus, the FGD will add a new particulate emissions source at this facility; offsetting some of the reduction achieved by the sulfur-removing FGD system.

- (c) An FGD system, regardless of the type, will require disposal of the spent reagent. Since space is limited at this site, the disposal will most likely take place at a “new” landfill. Thus, in addition to the cost necessary for the FGD, a suitable landfill site would need to be identified and a permit would need to be obtained. This would be a significant undertaking and not especially productive given other non-FGD processes are available.
- (d) The non-FGD processes described earlier are more efficient at reducing sulfur compounds from entering the atmosphere than FGD. The control efficiencies for FGD would likely peak at about 80 to 90% (due to low concentration streams). Non-FGD units are expected to be significantly better.
- (e) For wet scrubber FGD, a complete water system, including disposal, would be required. This is clearly unnecessary given other alternatives and the potential environmental consequences.
- (f) To our knowledge, no FGD system has been installed at any gas processing facility such as the Tioga plant. This fact makes it clear that an FGD system is not a viable option for consideration.
- (g) Finally, it is noted that the WRAP 2009 4-Factor analysis did not itself address nor consider FGD as an available technology. There was no discussion or cost estimates for this control technology.

For all of the reasons above, it was decided to not pursue the FGD option further and it was dropped from analyses that follow.

Amine Gas Sweetening Unit (NO_x)

The amine gas sweetening unit at the Hess Tioga Gas Plant facility contains no NO_x post-control technologies. NO_x emissions from these units are typically very small, negating the need for post controls. Hess had suggested to NDDH that it was not necessary to conduct a 4-Factor analysis for this pollutant/unit. It was later discovered that a published emission factor was available for this unit.¹⁶ Despite a low emission rate for this unit (≈ 50 tons/year) an NO_x analysis proceeded.

A review of the literature indicates that the only practical technology that might be applied to this unit would be Selective Catalytic Reduction (SCR). SCR technology and its requirements and limitations are explained in detail below in the Compressor Engines section. For the sake of brevity, it will not be repeated here. For purposes of our analysis, however, it has been assumed that such a technology might achieve 90% reduction in actual emissions.

Although a cost analysis has been conducted for this technology, it is not a foregone conclusion that such an application of SCR would be useful for Round 2. The emission reduction is small from a mass point of view. In addition, we are not aware that SCR has ever been applied at an amine unit anywhere in the US or elsewhere.

Compressor Engines (NO_x)

The compressor engines at the Tioga facility drive compressors that boost the inlet field gas pressure for processing. The engines are fueled by a portion of the gas stream (pipeline quality fuel gas) produced by the plant. The exhaust gases from each compressor engine are released to the atmosphere through individual stacks.

The seven Clark Engines that have been identified by NDDH are large integral engines; i.e. the engines themselves and the compression structure are constructed as a single unit. Thus, replacement of these engines would be extraordinarily expensive and difficult as both the compression and engine would need to be replaced. Regardless, there are five 1,950 horsepower (hp) engines and two 2,250 hp engines. The two 2,250 hp engines were modified in 2004 by adding turbocharging systems and other means to lower emissions. The emissions from these two engines are about 75% less than the other engines and as such were not subject to additional analyses. The remaining five engines have not been substantively updated since they were installed in the 1950's although they have been maintained in good working order since.

¹⁶ Emission Factor = 0.1 lb/10⁶ BTU (AP-42, Table 8.13-2, April, 2015)

Three control options were assessed for the five 1,950 hp Clark Engines: Low Emission Controls (LEC); Select Catalytic Reduction (SCR), and converting engines from gas to electric power.

i) **Low Emission Controls (LEC)**

LEC application includes various upgrades, modifications, and engine tuning improvements. These typically include a combination of turbocharging [increases air-to-fuel (AFR) ratio], intercooling, enhanced mixing (high pressure fuel injection) and an increase in ignition energy.¹⁷ LEC is the preferred approach to reduce lean burn engine NOx emissions when compared to alternative options such as SCR.¹⁸

LEC modifications provide additional air to a controlled engine which, as a result, reduces maximum combustion temperature and minimizes NOx formation. Excess air may hinder combustion of the air-to-fuel ratio in the cylinder, so a high energy ignition source is generally required for engines equipped with LEC. Pre-chamber combustions systems are generally used to aid in combustion, however the power operating range may decrease on two-stroke cycle engines as a result of an LEC conversion. The term “LEC” is often used broadly to describe a number of technology approaches that can be used depending on the engine and NOx emission limit. Normally, multiple LEC related technologies may be required. Therefore, LEC system modifications assessed for the 5 Hess compressor engines were assumed to be on the high end of any given range of costs.

The reduction in NOx emission rates expected from the application of LEC is roughly 70% to 90% (The same reduction may be expected for SCR). For purposes of this 4-Factor analysis and as a matter of consistency among the engines and control technologies (LEC vs SCR), it was presumed that each technology can achieve a controlled emission rate of 1 g/bhp-hr. This emission rate is about the same as a 90% reduction depending on the specific engine and technology. In addition, 1 g/bhp-hr is the emission rate applicable to most new internal combustion engines.¹⁹ Since LEC would be applied to a set of older existing engines, the applied emission rate is conservatively low.

ii) **Select Catalytic Reduction (SCR)**

SCR is an exhaust control that could be applied to lean combustion engines which reduces NOx emissions by reacting NOx with ammonia or urea over a catalyst. Ammonia or urea is injected into the stream and requires a precise feed-rate based on the NOx

¹⁷ “Potential Impacts of the Ozone and Particulate Matter NAAQS on Retrofit NOx Control for Natural Gas Transmission and Storage Compressor Drivers,” Interstate Natural Gas Association of America (INGAA), Report No. 2016-6, December 2017. <https://www.ingaa.org/File.aspx?id=33789>

¹⁸ “Availability and Limitations of NOx Emission Control Resources for Natural Gas-Fired Reciprocating Engine Prime Movers Used in the Interstate Natural Gas Transmission Industry.” INGAA Foundation. July 2014. <https://www.ingaa.org/Foundation/FDNreports/NOx.aspx>

¹⁹ 40 CFR 60, Subpart JJJJ, Table 1.

concentration and the NO/NO₂ ratio of the NO_x. This feed rate, coupled with a narrow temperature range, is critical. If the ammonia feed rate is too low, then the targeted reduction in NO_x is not achieved; thus, failing in the agency's intent to improve regional visibility. If the ammonia rate is too high, then free ammonia is released. The ammonia will itself react in the atmosphere to form compounds such as ammonium sulfate(s) and ammonium nitrate(s). Both compounds are the primary 'culprit' that has led to the already observed regional haze concern. Thus, an improper feed rate will lead to a worsening of regional haze rather than making an improvement.

The process works by ammonia (the reagent) reacting with NO_x on a catalyst bed to form water and N₂. The reaction is characterized as follows:

While SCR has enjoyed a fairly wide applicability in power generation sources, its application to U.S. gas transmission sources has been very limited per INGAA 2014. That analysis details a number of the difficulties of applying SCR to gas transmission engines. These include:

- a) There are numerous technical concerns about SCR's application to compressor engines. Among them are exhaust temperature requirements, reagent control, and the treatment of potential variations in the reciprocating engine exhaust NO/NO₂ ratio.
- b) SCR has been more commonly applied to larger utility scale turbines and boilers and rarely used in compressor engines such as the Tioga facility.
- c) The use of SCR is most effective when operating in the exhaust temperature range of 480 to 800°F. The typical exhaust temperature range for some lean burn engines may present challenges because the minimum operating temperature of the catalyst is dependent on the composition of the exhaust gases and the type of catalyst materials used.
- d) Engines that have variable power loads, such as the case here, require more sophisticated controls to inject the proper amount of reagent, and it is not evident that robust control schemes have been developed for transmission applications.
- e) The installation of a continuous emissions monitor could be required to effectively control the amount of reagent necessary to achieve the desired NO_x emission rate.
- f) SCR catalytic elements can be contaminated by byproducts of combustion (such as oil ash) and more importantly here; engine oil carryover. Cleaning and replacement is required on a periodic basis, and extra management is required to ensure adequate inventories of reagent are maintained.

While EPA claims that SCR is a technology applicable to compressor engines²⁰ SCR has, in fact, rarely been used in the natural gas transmission and related industry.²¹ This does provide strong support for its use in this case.

LEC is nearly universally preferred over SCR for existing lean burn engines due to the issues described above. LEC works to prevent NOx formation while SCR acts to control already formed NOx in the exhaust stream.

iii) *Electric Compressors*

The third option under (initial) consideration is replacing these natural gas-fired integral (engine + compressor as a single unit) units with an electric powered unit. This possibility has been rejected, however, because such an option does not fall within the suggested EPA Guidance for the identification of alternative controls.²²

More specifically, the EPA Draft Guidance document discusses (relying on BART policies) the options that may or should be considered in identifying 4-Factor (via BART) control options. The Draft Guidance contains the following discussion (in identifying technologies outlined by BART and acceptable to the 4-Factor analysis):

*“Potentially applicable retrofit control alternatives can be categorized in three ways. Pollution prevention: use of inherently lower-emitting processes/practices, including the use of control techniques (e.g., low NOx burners) and work practices that prevent emissions and result in lower “production-specific” emissions (note that it is **not our intent to direct States to switch fuel forms, e.g., from coal to gas**), ...”* (emphasis added). EPA Draft Guidance, p 180.²³

This comment alone suggests that a fuel switch is not necessarily within the realm of a 4-Factor analysis. Clearly a switch from natural gas to electricity is, in effect, a fuel switch and not the intent of the analysis. The document goes on to provide a more specific discussion:

*“We do **not consider** BART as a requirement to **redesign the source** when considering available control alternatives. For example, where the source subject to BART is a coal-fired electric generator, we do not require the BART analysis to consider building a natural gas-fired*

²⁰ “Air Pollution Control Technology Fact Sheet,” SCR, EPA-452/F-03-032.

²¹ INGAA Foundation, *op. cit.*

²² *Draft Guidance on Progress Tracking Metrics, Long-term Strategies, Reasonable Progress Goals and Other Requirements for Regional Haze State Implementation Plans for the Second Implementation Period*,” EPA, EPA-457/P-16-001, July 2016.

https://www.epa.gov/sites/production/files/2016-07/documents/draft_regional_haze_guidance_july_2016.pdf

²³ *Ibid.*

*electric turbine **although** the turbine may be **inherently less polluting** on a per unit basis.” (emphasis added). EPA Draft Guidance p. 198.²⁴*

Again, the Draft Guidance suggests that one does not need, nor should, consider what amounts to be a redefinition or fundamental change in the underlying facility/unit. If EPA rejects changing an electrical generation plant from coal-fired to a gas-fired turbine as inappropriate, the same logic applies here (gas-fired to electric).

For the reasons above, replacing these gas-fired engines with electric engines has been removed from further consideration.

Flares (SO₂ & NO_x)

The acid/wet gas flare (S-101) and high-pressure flare (S-102) operate intermittently at the Hess facility to combust off-spec gas and to address emergency/malfunction events. Both sources are to be assessed for additional NO₂ and SO₂ control. Additional control equipment systems for flare sources are not known or available for a facility whose emission rate is highly variable in both time and quantity. As a result, we are not able to identify any available control technologies for these two specific flares.

Even if a control technology were to present itself, the annual emissions from these two flares would almost certainly yield cost/ton of removal values that are not cost-effective. As evidence, the most recent 2-year average annual emissions for these two flares were:

SO₂

S-101 = 21 t/yr @ 79 hours of operation per year

S-102 = 40 t/yr @ 103 hours of operation per year

NO_x

S-101 = 0.0 t/yr @ 79 hours of operation per year

S-102 = 4.6 t/yr @ 103 hours of operation per year

The low total emissions produced by the flare sources would result in a high cost effectiveness in \$ per ton of emissions reduced since the total cost of implementation would only have the potential to control a minimal quantity of emissions. As a result, no further analyses were conducted for this source.

²⁴ Ibid.

3.1 Factor 1: Cost of Compliance

The cost of compliance estimates the capital cost of purchasing and installing new control equipment along with the annual operation and maintenance (O&M) cost as generally outlined in EPA Draft Guidance. The 2009 WRAP analysis also delineated these cost parameters into the following categories: direct capital cost, indirect capital cost, labor cost, contingency cost, and annual cost. Methodologies given in the EPA Air Pollution Control Cost Manual (Control Cost Manual) are the indicated reference for determining the cost of compliance as directed by the EPA Draft Guidance.²⁵ Costs were expressed in terms of cost-effectiveness in a standardized unit of dollars per ton of emissions reduced by the proposed control option. The cost of compliance is analyzed by source/source group within Table 2 and the following sections.

²⁵ EPA Cost Control Manual (sixth edition): <https://www.epa.gov/economic-and-cost-analysis-air-pollution-regulations/cost-reports-and-guidance-air-pollution#cost%20manual>

Table 2: Estimated Costs of Control Options for Hess Tioga Gas Plant Sources

Source	Potential Control Option	Pollutant	Estimated Control Efficiency (%)	Potential Emission Reduction (tons/year)	Estimated Capital Cost (\$1000)	Estimated Annual Cost (\$1000/year)	Cost Effectiveness (\$/ton)
Amine Gas Sweetening Unit (SRU)	SCOT (or equivalent)	SO ₂	90%	539	16,750	6,369	\$11,815
	SCR	NO ₂	90%	53	1,204	1,127	\$23,623
Compressor Engines (Mean among 5 engines)	LEC	NO ₂	1 g/bhp-hr ^a	134	4,000	996	\$7,951 ^b
	SCR	NO ₂	1 g/bhp-hr ^a	134	877	502	\$4,710 ^c
Flares (2)	N/A	SO ₂	--	--	--	--	--
	N/A	NO ₂	--	--	--	--	--

^a Emission reduction is assumed to achieve approximately 1 gram/bhp-hour.

^b Cost effectiveness per engine ranged from \$13,123 to \$5,401. Individual values are found in Appendix A.

^c Cost effectiveness per engine ranged from \$8,917 to \$3,879. Individual values are found in Appendix A.

3.1.1. Amine Gas Sweetening Unit

SO₂

The cost estimate of a SCOT unit includes the capital cost of constructing the system which comprises the reactor, cooling tower and scrubber systems. Again, the SCOT system has been assessed specifically, however it is presumed to be a representative selection for all potential add-on TGST controls. The cost estimate also includes direct and indirect costs associated with modifying the current 2-Stage Claus / CBA unit to accommodate the SCOT (or equivalent) system. Indirect costs include engineering design, permitting, construction and field expenses, contractor fees, start-up, performance testing, and contingencies. Estimated costs are delineated in Appendix A. The calculated costs included in Table 2 have been adjusted to reflect value in 2017 per the Consumer Price Index. Design, construction, and operation of a SCOT system with the Hess amine sweetening unit is projected to cost approximately \$11,815 per ton of SO₂ removed.

NO_x

To complete the analysis, a cost-effectiveness investigation was conducted for NO_x. As noted earlier, the emission rate at this source is small and has, no doubt, an insignificant impact on regional haze. Regardless, a cost analysis was completed for SCR. Using the capital cost estimates found in EPA's Air Pollution Control Technology Fact Sheet, SCR, EPA-452/F-03-032, Table 1a, the cost effectiveness for controlling NO_x was estimated at \$23,623/ton removed.²⁶ This value is well outside normal BACT and BART ranges and thus is removed from further consideration.

3.1.2. Compressor Engines

The Clark Engines analysis included estimated costs for updating each of the five 1,950 hp with either LEC or SCR.

LEC.

The LEC analysis is based on various upgrades and changes to the 5 engines. As a general rule, an upgrade to LEC consists of:

- Hardware and engineering costs for replacing the existing cooling systems with water pump systems to eliminate boil-off cooling.
- Field service, repairs, and parts replacement for zero-hour overhauls.
- Hardware, installation, and commissioning of a HPfi fuel injection upgrade that needs to include:
 - A single "Balance of Plant" engineering and hardware support for multiple engine revamps.
 - Hardware, installation, and start-up of the HPFi equipment.

²⁶ Details of the calculation are found in Appendix A.

The cost of such upgrades is dependent on numerous factors. A literature search did not yield definitive results. There are several earlier reports, NESCAUM – 2000,²⁷ for example, that provided a wide range of expenses. There is, however, a recent report (December 2017) from the INGAA Foundation that provides a cost range for LEC upgrades.²⁸ That report addressed the cost of LEC for natural gas-fired compressor engines, among others. In particular, it provided a range for Clark engines of similar size to the 5 engines at Hess.

The report suggests a range of: \$1,250 to \$2,500 per hp from a base model of 1,600 hp. The engines at issue are 1,920 hp. It was decided that an upper range value would be appropriate in this analysis due to the larger size of engine and the age of these 1950-era units.

In addition, the typical calculation for determining the cost effectiveness (\$/ton reduction) begins with the capital expenses. Then adjustments are made to include instrumentation, freight, foundations, electrical, etc. In this case, however, the INGAA report implies that these figures (\$/hp) are the “total cost.” It is not clear from the report if that cost (\$1,250 - \$2,500) includes foundations, electrical, piping, etc. To be conservative, it was decided to assume that the report costs included this direct installation costs. To that end, the presented data in the report and appendix remove the EPA-suggested cost adjustments for foundations and the like by assuming that those costs are already included in the base cost (\$1,250 - \$2,500). Should this not be the case, then the cost effectiveness will be increased appropriately.

Using this information, an annual cost of roughly \$1,000,000 is estimated for each engine. Details of the calculations are found in Appendix A. This cost coupled with the various emission rates for each of the five engines yielded a cost effectiveness ranging from \$5,401 to \$13,123 per ton of NOx removed. The average cost effectiveness among the 5 engines was \$7,951.

SCR.

The capital costs for SCR, if one were to assume this was an ‘achievable technology’ for this application, are varied. There are a number of published cost estimates for typical coal- oil- and gas-fired medium to large sized boilers. The same cannot be said for a retrofit of a natural gas-fired compressor engine/compressor.

In addition, the cost of retrofit SCR is much higher than an original installation which would apply to this analysis. SCR systems used to retrofit an existing unit increase costs around 30%²⁹ more due to ductwork modification, the cost of structural steel, reactor construction

²⁷ “Status Report on NOx Controls for Gas Turbines, Cement Kilns, Industrial Boilers, Internal Combustion Engines Technologies & Cost Effectiveness, Northeast States for Coordinated Air Use Management (NESCAUM), December 2000.

²⁸ “Potential Impacts of the Ozone and Particulate Matter NAAQS on Retrofit NOX Control for Natural Gas Transmission and Storage Compressor Drivers,” Interstate Natural Gas Association of America (INGAA), Report No. 2016-6, December 2017. <https://www.ingaa.org/File.aspx?id=33789>

²⁹ EPA Air Pollution Control Technology Fact Sheet – SCR: <https://www3.epa.gov/ttn/catc1/dir1/fscr.pdf>

and so forth. O&M costs may also be substantially dependent on reagent usage, catalyst replacement, and increased electrical usage. These costs are also impacted by the overall capacity – which determines reagent and catalyst volume – and annual versus season operations schedule. The average (all 5 engines) cost effectiveness of SCR was \$4,710 per ton removed. Individual engines ranged from \$3,879 to \$8,917. This cost effectiveness range coupled with multiple technical difficulties and its non-use in this general application does not make it an attractive Round 2 candidate.

The derivation of the capital cost figures, emission rates and other general information may be found in the appropriate tables in Appendix A.

3.2 Factor 2: Time Necessary for Compliance

Per the EPA Draft Guidance, the provisions for this factor within the BART guidelines should be utilized to estimate time necessary for compliance. Additionally, the best guide to determine time necessary for compliance is prior experience with the planning and installation of new emission controls. Source-specific factors should be considered as well.

EPA has estimated that it takes approximately 30 months to design, permit, build, and install a typical SO₂ scrubbing control unit for a single source. No specific data was located as it regards the SCOT unit (or its equivalent). Using the EPA estimate as a guide, their analysis also determined that 12-months is additionally required for a project including the installation of control equipment on multiple sources. Another 12 months may be required for staging the installation process across the multiple sources. Finally, it is generally recognized that facilities may require a 1 year (or more) for the procurement of project funding.

As a result, the time necessary for compliance for the SCOT unit is estimated at approximately five years. This time period accounts for about one year of capital acquisition; two to three years for designing, permitting, constructing, and installing the control equipment; and one year for installing controls for multiple components in stages.

A longer timeline would also be expected for the LEC conversion for the five engines discussed in this report. The installation, tuning and integration would need to be executed in a sequential fashion in order to keep the facility in operation during this time. This will stretch the 'time necessary for compliance.' No specific time-line is offered at the time of this report. However, it would be reasonable to suggest that the time needed would be at least five years and possibly more.

Although no specific data was found, it would be reasonable to assume that a five-year period would also be appropriate for the installation of SCR in lieu of LEC should that be required. Finally, it was further reasoned that this five-year period serves as an estimate for the time necessary for installation of an SCR unit on the Amine Sweetening Unit, although its installation is not justified for cost effectiveness reasons.

3.3 Factor 3: Energy and Non-Air Quality Environmental Impacts of Compliance

The provisions of the BART Guidelines are recommended for assessing both energy and non-environmental impacts. The EPA Draft Guidance states that an energy impacts assessment should be considered in terms of kilowatt-hours or mass of fuels used accounting for direct energy consumption cause by control implementation. Indirect energy inputs to produce the raw materials for construction of equipment should be excluded from the analysis. The Control Cost Manual is the preferred reference and provides advice on estimating energy requirements. Non-air environmental may include the cost associated with solid waste disposal, wastewater discharge, acid or nitrogen deposition, and climate impacts.

3.3.1. Amine Gas Sweetening Unit

Two secondary waste streams are generated when using the SCOT unit TGST according to the EPA Pollution Control Technical Manuals (PCTMs). A sour water stream is generated from the quench tower due to condensation of water vapor present in the reduction effluent stream. A sour water stripper treats the sour water stream and any remaining H_2S or NH_3 is recycled into the Claus feed stream. Additionally, a second waste stream consists of spent catalyst from the reduction reactor. A SCOT system initially requires approximately 28% wt of the initial Claus catalyst requirement. According to the EPA PCTMs, this equates to 850 kg catalyst per kmol/hr H_2S converted from SO_2 , COS , and CS_2 . Catalyst has a typical service life of about 24,000 hours. Thus, the spent catalyst will require disposal about every four years. The implications of disposal of this waste stream has not been analyzed at this time since the cost effectiveness does not make its use a practical alternative.

There is also an energy cost associated with this added level of emission controls. It has been estimated that this level of technology would require about 700 kW-hr of use.³⁰

3.3.2. Compressor Engines

SCR.

SCR control systems require the use of aqueous ammonia, anhydrous ammonia, or urea-to-ammonia reagents for the reduction reaction. Systems that use urea produce aqueous ammonia onsite. Anhydrous ammonia is nearly pure ammonia gas and must be transported and stored under pressure. Anhydrous ammonia is classified as a hazardous material which often requires special permits as well as additional procedures for transportation, handling and storage. Systems using

³⁰ "Supplementary Information for Four-Factor Analyses for Selected Individual Facilities in North Dakota", Brad Nelson, William Battye, Janet Hou, EC/R Incorporated, Western Regional Air Partnership (WRAP) and Western Governors' Association (WGA), May 18, 2009, Table 4-3.

aqueous ammonia transport and store the reagent concentration in water, generally 19% - 29+% ammonia to water.³¹ While aqueous ammonia can be safer to transport and store, the diluted ammonia concentration requires more storage capacity than anhydrous ammonia and requires shipping costs for the water solvent in the solution. Hess would be required to account for additional chemical storage, protection, and permitting with the additional reagent solution stored on site.

Additionally, SCR systems utilize catalysts to aid in NOx control. The catalysts are generally composed of active metals or ceramics with a highly porous structure. Activated sites are located within the pores of the catalyst and these sites have an acid group on the end of the compound structure where the catalytic reduction reaction occurs. The catalyst material reactivates via rehydration or oxidation after the reduction reaction occurs. This is a limited process, however, and over time the catalyst activity decreases, requiring replacement, washing/cleaning, rejuvenation, or regeneration of the catalyst. Catalyst storage, transport, and disposal must then be accounted for in the SCR control viability analysis.

An estimate was made of the aqueous ammonia feed rate necessary for the facility. It is estimated that with all 5 engines in operation, a feed rate of about 70 gallons per hour would be necessary.³² To handle this much material would require a large storage tank (\approx 5,000 gallons) that would need recharged about every 3 days. To provide a more reasonable recharge rate (10^+ days) would require a much larger tank(s). In either case, the storage or use of this quantity triggers the requirements of the accidental release program found in 40 CFR 68.³³ Depending upon specifics, a detailed amendment to the risk management plan (RMP) must be developed and implemented under this program. This only adds another layer of regulatory reporting along with an unnecessary risk by itself. The fact that such a plan would be required dampens its attractiveness for consideration.

LEC.

The LEC technology does not require the handling or storage of hazardous materials as is the case for SCR. The LEC technology does not require, on its face, changes in pressure drop across any system that could create an energy demand penalty.

³¹ EPA Cost Control Manual (sixth edition): <https://www.epa.gov/economic-and-cost-analysis-air-pollution-regulations/cost-reports-and-guidance-air-pollution#cost%20manual>

³² See general calculations and data found in Appendix A (from EPA Cost Control Manual).

³³ The program is triggered for aqueous ammonia use or storage greater than 20,000 pounds. The quantities described exceed this value.

3.4 Factor 4: Remaining Useful Life

The Hess Tioga Gas Plant remaining useful/service life is not specific at this time. As discussed in the 2009 WRAP Analysis, the service life of these emission sources at industrial facilities are difficult to estimate.

The startup dates for these units were:

Amine Sweetening Unit:	1991
Compressor Engines (5):	1954
Flares:	n/a

Regardless of the ability to select a particular time, the service life of the analyzed control technologies was approximately 15 years. The 15-year figure was used to amortize the capital costs of the add-on and modified (LEC for the compressor engines) emission controls. Given the historical perspective, it is reasonable to conclude that the remaining life of the facility (Sweetening Unit and Engines) itself is expected to exceed the 15-year life of the control equipment.

The capital cost of the control equipment would need to be amortized over a shorter period if the remaining life of an emission source is less than the projected life of the new control equipment. Since this was not the case, the remaining equipment life of the facility is expected to equal or exceed the life of the analyzed technology options.

4.0 CONCLUSIONS AND RECOMMENDED SELECTION

A 4-Factor analysis has been conducted for the Hess Tioga facility. The analysis was conducted to meet the requirements of “Round 2” to develop of a State Implementation Plan (SIP) to address Regional Haze. Regional haze requirements and goals are found in Section 169A of the Federal Clean Air Act and codified in 40 CFR 51.308(d)(1). To implement the requirement, the North Dakota Department of Health (NDDH) submitted a letter to Hess dated May 18, 2018, seeking such an analysis.

The 4 factors to be analyzed based on the NDDH letter and the regional haze rule were:

- Factor 1. Cost of compliance
- Factor 2. Time necessary for compliance
- Factor 3. Energy and non-air quality environmental impacts of compliance
- Factor 4. Remaining useful life of any existing source subject to such requirements

NDDH then requested a 4-Factor analysis for SO₂ and NO_x for the following source groups:

- 1. Amine Gas Sweetening Unit (S-302)
- 2. Clark Compressor Engines (C1A – C1G)
- 3. Flares (S-101 and S-102)

The emitting units were analyzed for these factors in general accordance with EPA's Draft Guidance.³⁴ The details of those results were presented in prior sections of this report.

³⁴ *Draft Guidance on Progress Tracking Metrics, Long-term Strategies, Reasonable Progress Goals and Other Requirements for Regional Haze State Implementation Plans for the Second Implementation Period*,” EPA, EPA-457/P-16-001, July 2016.
https://www.epa.gov/sites/production/files/2016-07/documents/draft_regional_haze_guidance_july_2016.pdf

Amine Gas Sweetening Units.

SO₂

Two control technologies were originally considered for this unit-pollutant combination: Tail-gas scrubbing treatment (SCOT) and Flue-gas desulfurization (FGD). The SCOT technology (or its equivalent) essentially extends the basic Claus reaction by collecting sulfur gasses (primarily SO₂ and H₂S), concentrating them, and then recycling the gasses back to the Claus plant. The FGD system, typically found in a coal-fired power plant, treats exhaust gas with an alkaline reagent (usually CaO or CaCO₃) to remove SO₂. The spent reagent (CaSO₃ or CaSO₄) is then collected in a fabric filter unit in which the collected dust must be treated in a licensed landfill.

It is concluded that the FGD system is not practical nor appropriate for this application. Those reasons include (but not limited to):

- A new emitting source (particulate) would be added to the plant offsetting some of the benefits of a reduction in SO₂;
- A new disposal system would be required to treat the spent reagent,
- FGD has never, to our knowledge, been used in treating SO₂ emissions from any gas processing facility; and
- The prior (2009) 4-Factor analysis for this facility did not identify nor consider FGD as a viable technology.

The SCOT technology (or its equivalent) was analyzed. While the technology may be applied to a facility like the Tioga plant, it was rejected due to its high cost effectiveness (≈ \$12,000/ton).

NO_x

Although the emission rate of NO_x from the unit is very low, an analysis for this unit was conducted for thoroughness. The technology identified most probable for this unit is Selective Catalytic Reduction (SCR). SCR was rejected as inappropriate for numerous reasons, including its high cost effectiveness (≈ \$23,000/ton). Therefore, SCR is not a candidate for Round 2 emission reductions.

Compressor Engines.

NO_x

There were two control technologies identified for reducing NO_x from these units: SCR and Low Emission Control (LEC).

LEC is a system of upgrades, modifications and tuning of the engines to achieve a lower emission rate. LEC could, theoretically, be applied to each of the 5 compressor engines subject to this analysis.

The cost effectiveness of this technology was excessive. The average cost effectiveness was \$7,951/ton for all 5 engines. The engine-by-engine cost effectiveness ranged from roughly \$5,400 to as high as \$13,100 depending on the engine. Since these values are considered excessive, LEC has been removed from consideration for Round 2.

SCR was also analyzed as a potential control technology. However, SCR is rarely, if ever, used for this type of application. Evidence of that stems from several reports. One recent study (2014) makes the following comment: *“To date, SCR application to U.S. gas transmission sources has been very limited, and SCR has not been applied to an existing integral engine.”*³⁵ The 5 engines at the Tioga facility are existing integral engines as described in the report. In addition, an even more recent report failed to consider SCR a noteworthy technology for reducing NO_x emissions from transmission and storage compressors as a means of achieving the ambient NO_x standards.³⁶

Additionally, SCR carries the burden of handling and storing either anhydrous ammonia (NH₃) or aqueous ammonia (NH₄OH). This would require new equipment in which to transport and handle this material. In both cases, the storage quantities necessary will trigger the need for a Risk Management Plan (RMP) required by the Accidental Release program (40 CFR 68) in order to address the potential of a spill or release that could have public health implications. The addition of this equipment constitutes an unnecessary risk for the purpose of regional haze.

In addition to the burdens described, the efficacy of the control technology is at issue. For SCR to work effectively, a precise ammonia feed rate

³⁵ “Availability and Limitations of NO_x Emission Control Resources for Natural Gas-Fired Reciprocating Engine Prime Movers Used in the Interstate Natural Gas Transmission Industry.” INGAA Foundation. July 2014, Page 9. <https://www.ingaa.org/Foundation/FDNreports/NOx.aspx>

³⁶ “Potential Impacts of the Ozone and Particulate Matter NAAQS on Retrofit NO_x Control for Natural Gas Transmission and Storage Compressor Drivers,” Interstate Natural Gas Association of America (INGAA), Report No. 2016-6, December 2017. <https://www.ingaa.org/File.aspx?id=33789>

coupled with a narrow temperature range are necessary. Both conditions would be difficult to maintain due to varying loads on the compressor engines themselves.

Finally, the cost effectiveness of SCR is, overall, excessive. The average cost effectiveness was \$4,951 for all 5 engines. The engine-by-engine effectiveness ranged from roughly \$3,900 up to \$8,900. Due to these costs, the technical concerns, the need to handle hazardous materials and the nearly universal lack of use of SCR for legacy compressor engines, SCR is rejected for Round 2 purposes.

Flares.

NO_x and SO₂

A review of the literature does not yield any 'available' control technology to control either NO_x or SO₂ emissions from these highly intermittent sources such as the Tioga flares. The flares primarily serve emergency and other upset conditions. For example, each flare operated 0.1% of the time in the past 2 years. Clearly, any control technology, even if it were available, would not have a measurable impact on the regional haze long-term goals. Because no reasonable technology is available, and no measurable regional haze benefit would be realized, it is concluded that there are no technology options available for these sources.

Following a careful review of the information it is concluded that additional emission controls and limitations for these sources are not necessary to make reasonable progress based on the 4-Factor analysis.

David,

In response to the Department's request for a four-factor analysis concerning emissions of sulfur dioxide (SO₂) and nitrogen oxides (NO_x) at Hess's Tioga Gas Plant (letter request dated May 18, 2018), please find attached our report, which has been prepared in consultation with Bison Engineering Inc and guidance from the Department.

Should you have any questions after your review of our submittal, please do not hesitate to contact me for additional clarification or information.

Regards,

Tony St. Clair, P.E., BCEE, QEP, REM
Advisor, EHS - Environmental & Regulatory

EXECUTIVE SUMMARY

Bison Engineering, Inc. was retained by Hess Corporation to prepare a 4-Factor analysis for specific units located at their Tioga Gas Plant located at Tioga, ND. The 4-Factor analysis was requested by North Dakota's Environmental Health Section, Division of Air Quality in a letter dated May 18, 2018.

The analysis itself relates to "Round 2" of development of a State Implementation Plan (SIP) to address Regional Haze. Regional haze requirements and goals are found in Section 169A of the Federal Clean Air Act and codified in 40 CFR 51.308. The purpose of the 4-Factor analysis is, to determine if there are control options at Hess to reduce emissions that could be used to attain "reasonable progress" toward the state's visibility goals.

The 4-Factor analysis was conducted on three source groups at the Hess facility: amine sweetening unit, compressor engines and flares. The results of the analysis have indicated that additional controls on these units are not necessary to make reasonable progress due to costs and other considerations. It is concluded that these sources do not qualify for additional emission controls or limitations based on the 4-Factor analysis.

APPENDIX B: BASELINE EMISSIONS	

1.0 INTRODUCTION

With the 1977 amendments to the Federal Clean Air Act (42 USC 7401 *et. seq.*) Congress declared as a national goal “... *the prevention of any future, and the remedying of any existing, impairment of visibility in mandatory class I Federal areas which impairment results from manmade air pollution.*” [42 USC 7491(a)(1)]. With that goal, plans and requirements were eventually codified in the Code of Federal Regulations primarily in 40 CFR 51.308. (The entire visibility program is found in 40 CFR 51.300 → 309). Individual states are required to establish “reasonable progress goals” [40 CFR 51.308(d)(1)] in order to “attain natural visibility conditions” by the year 2064 [§308(d)(1)(i)(B)].

The state of North Dakota has met the first round of those obligations with the establishment of Best Available Retrofit Technologies (BART) for various sources. A second round of obligations is now under development. The Regional Haze Rule (RHR) requires an additional step toward ‘reasonable progress’ in meeting the national goal.¹ The RHR identifies four factors which should be considered in evaluating potential emission control measures to make reasonable progress toward the visibility goal. These are as follows:

- Factor 1. Cost of compliance
- Factor 2. Time necessary for compliance
- Factor 3. Energy and non-air quality environmental impacts of compliance
- Factor 4. Remaining useful life of any existing source subject to such requirements

These four factors are collectively known as the 4-Factor analysis.

To implement the requirement, the North Dakota Department of Health (NDDH) submitted a letter to Hess dated May 18, 2018. The letter noted that NDDH needed to address 80% of the visibility impairment caused by ND sources.² According to NDDH, visibility data from the IMPROVE ambient monitoring sites at Theodore Roosevelt National Park (TRNP) and Lostwood Wilderness Areas indicate that sulfates and nitrates (via SO₂ and NO_x; respectively) are the largest contributors to visibility impairment.³

In order to determine which ‘nearby’ sources should be subject to a 4-Factor analysis, NDDH conducted a Q/d (emissions/distance) analysis of SO₂ and NO_x for industrial

¹ The national goal is to attain natural visibility conditions in mandatory Class I areas by the year 2064 [40 CFR 51.308(d)(1)(i)(B)].

² According to NDDH this value is derived from information contained in EPA’s Draft Guidance on Progress Tracking Metrics, Long Term Strategies found at: https://www.epa.gov/sites/production/files/2016-07/documents/draft_regional_haze_guidance_July_2016.pdf.

³ Hess does not necessarily agree or disagree with this assessment at this time. Hess is providing the information in this document as requested by NDDH.

sources within the state. That analysis has indicated that there are three Hess sources (or source groups) that warrant the analysis according to NDDH. These sources are:

1. Amine Gas Sweetening Unit (Emission Unit S302)
2. Clark Compressor Engines (Emission Units CIA- CIG)
3. Flares (Emission Units S101 and S102)

Therefore, NDDH has requested HESS conduct a 4-Factor analysis for these units to assess potential reductions in SO₂ and NO_x emissions. The May 18 letter and followup communication requested the analysis be completed no later than March 15, 2019.

Although NDDH requested an analysis of both SO₂ and NO_x for all three source groups, subsequent analysis prompted a small change to the request. Based on correspondence between Hess and NDDH⁴, it was agreed no robust analysis was necessary for SO₂ for the Clark Compressor Engines. Since these engines are fired with pipeline quality natural gas, there are no substantive SO₂ emissions from this source category. A similar conclusion was reached with respect to NO_x emissions from the Amine Gas Sweetening unit. At the time of the email correspondence it was believed that NO_x emissions from these units are low, so there would be no real visibility benefit by attempting to add additional NO_x controls. However, subsequent review found a published emission factor for these units. The published factor indicated a low emission rate, as suspected. However, since an emission rate was available, it was decided to proceed with an analysis even though the reduction in NO_x, should additional controls be added, would not yield any measurable improvement in visibility.

Based on the discussion above and agreement with NDDH⁵, no formal SO₂ analysis was conducted for the compressor engines. For completeness, an NO_x review was conducted for the Amine Sweetening Unit albeit with low actual emission rates.

The remainder of this document outlines the approach used to conduct the 4-Factor analyses along with a detailed analysis for each group.

⁴ Email to David Stroh from Tony St Clair (9/14/18) and associated reply (9/17/18)

⁵ Ibid.

2.0 APPROACH AND METHODOLOGY

The Tioga Gas Plant, the subject of this 4-Factor analysis, is located at 10340 68th Street NW in Tioga, North Dakota. The location is W½, NE¼ S26, T157N, R95W in Williams County. The plant is used to process natural gas from well sites for sale to customers.

Letters dated May 18, 2018 and January 16, 2019 from NDDH provided some recommendations for conducting the 4-Factor analysis. That information was supplemented based on an email from David Stroh (NDDH) to Tony St. Clair (Hess) which provided further discussion and recommendations (June 2018). The matter was again discussed in two conference phone calls between the staff of NDDH, Hess, and Bison Engineering on June 20, 2018 and January 30, 2019.

The most complicated or in-depth analysis of the four factors is Factor #1: Cost of Compliance. The NDDH email and phone conversation suggested this analysis should follow, in general terms, the methods conducted for a Best Available Control Technology (BACT) review. The agency made clear that this is not, in and of itself, a pure BACT analysis; only that the typical steps might be followed.

In addition to the direct contact with NDDH described above, EPA has provided draft guidance (EPA Draft Guidance) of its own for the entire Round 2 procedures including suggested methods for assessing the Cost of Compliance as well as the other 3 factors.⁶ That guidance was published in July 2016 as a draft. We are not aware that the Draft Guidance has been finalized. Nonetheless, since this was the most recent EPA guideline available, that document was consulted for conducting this 4-Factor analysis.

In general, the cost analysis uses the overall approach for BACT, but is modified by the EPA Draft Guidance⁷ and EPA's Control Cost manual⁸. The approach used in this analysis follows these recommendations and guidelines as much as practicable. The other 3 factors employed suggestions from the EPA Draft Guidance as much as reasonable or available data might have allowed.

3.0 4-FACTOR ANALYSIS

A 4-Factor analysis was completed for the three Hess sources/source groups selected by the NDDH Q/d analysis. The following outlines the analysis for each source using primarily the direction of the EPA Draft Guidance⁹ and the WRAP 2009 4-Factor analysis¹⁰.

The initial step in the 4-Factor analyses was to identify possible additional control options for each source or source group. The options chosen include control techniques addressed in guidelines published by the EPA, emission control cost models such as AirControlNET, Best Available Retrofit Technology (BART) analyses, White Papers prepared by the Midwest Regional Planning Organization (MRPO), and National Association of Clean Air Agencies (NACAA).

The options for each source/source category are summarized in the Table 1.

⁹ “Draft Guidance on Progress Tracking Metrics, Long-term Strategies, Reasonable Progress Goals and Other Requirements for Regional Haze State Implementation Plans for the Second Implementation Period,” EPA, EPA-457/P-16-001, July 2016.

Table 1: Additional Control Options by Source Group

Source	Emission Unit ID	Pollutant	Existing Controls	Control Efficiency (Existing)	Potential Additional Control Measures
Amine Gas Sweetening Unit (Sulfur Recovery Unit)	S302	SO ₂	2-Stage Claus + Cold Bed Adsorption (CBA) + tail gas incinerator	>98%	Oxidation or Reduction Options (Tail-Gas Scrubbing Treatment Unit, LO-CAT, Paques biological processes)
		_____		_____	Traditional Flue Gas Desulfurization (FGD)
		NO ₂		---	SCR
		SO ₂		>98%	Acid Gas Disposal via Injection Well
Clark Compressor Engines (Natural gas pipeline compressor engines)	C1A through C1G	NO ₂	Lean Burn Engines	---	Low Emission Combustion (LEC) - Turbocharge - Air-to-fuel - Ignition timing - Etc.
					SCR
					Electric Motor Replacement
Acid/Wet Gas Flare And High Pressure Flare	S101 and S102	SO ₂ NO ₂	None	---	Flare Management Plan

Amine Gas Sweetening Unit (SO₂)

The amine gas sweetening unit at the Hess Tioga Gas Plant facility controls sulfur dioxide (SO₂) emissions via two steps. The first is a 2-stage Claus process. This process converts hydrogen sulfide (H₂S) and SO₂ into elemental sulfur (S) via the 'Claus' reaction. The general reaction is: $\text{H}_2\text{S} + \text{SO}_2 \leftrightarrow \text{S} + \text{H}_2\text{O}$ (unbalanced). To drive the reaction toward completion, the facility further utilizes Cold Bed Adsorption (CBA) which allows this reversible reaction to proceed further. The CBA was installed in 1991. All-in-all the unit collectively reduces SO₂ emissions by 98+%.

Treatment Options

The most common control measures that may be applied to a typical refinery-based Claus facility (with or without CBA) are generally categorized as Tail-Gas Scrubbing Treatment units (TGST). These units use either an oxidation or a reduction measure to continue to convert the underlying sulfur gas to elemental sulfur. Another common measure of removing sulfur dioxide from a gas stream is a traditional Flue Gas Desulfurization (FGD) unit that is more typically used at coal or oil-fired electrical generating units. The final option which could be applied is injecting the gas into a deep well for disposal.

The TGST control typically adds an additional scrubbing process to the Claus exhaust stream prior to the tail-gas incinerator. The processes classically convert the Claus exhaust to either H₂S (reducing process) or SO₂ (oxidizing process). In either case, the 'newly created' H₂S or SO₂ is then, in most cases, returns these gases to the Claus or CBA portion of the facility to extend the elemental sulfur recovery.

There are a number of processes that achieve this aim. Regarding the oxidation method, the exhaust stream from the CBA would oxidize the various sulfur compounds (S, H₂S, COS ...) to sulfur dioxide. The sulfur dioxide is then concentrated and used in the Claus/CBA process itself. There are several varieties of processes within the oxidation method. They include the Stauffer, Wellman-Lord, and Aquaclaus. Only the Wellman-Lord process has been applied successfully in any US refinery.¹¹

The reduction process, however, is the more typical refinery-based method of additional sulfur dioxide control. This process converts the sulfur gases from the Claus (or CBA) to H₂S. The H₂S is then sent to a scrubber for removal prior to a tail-gas incinerator. The H₂S scrubber typically uses an amine process (similar to the amine unit itself) to capture the H₂S and then recycles this captured H₂S (now in a concentrated stream) back to the Claus plant.

Five common systems utilizing the reduction control method are the LO-CAT[®], Beavon, Beavon MDEA, Shell Claus Off Treatment (SCOT), and ARCO. The most common among these are the LO-CAT[®] and SCOT units. Additional oxidation-reduction processes

¹¹ AP-42, Section 8.13, 1995, p 8.13-4.

for converting H₂S into sulfur include Sulferox, Stretford, and Paques biological process. For the oxidation-reduction processes, LO-CAT® has been among the predominant industry choice.¹² LO-CAT® is a proprietary liquid redox process that converts H₂S in the acid gas to solid elemental sulfur using an aqueous solution of iron as catalyst. LO-CAT® units are in service treating refinery fuel gas, off gas, sour-water-stripper gas, amine acid gas, and Claus tail gas. The acid gas stream is compressed and fed to a LO-CAT® Absorber unit where it contacts a dilute, iron chelate catalyst solution and the H₂S is absorbed and oxidized to solid sulfur. Sweet gas leaves the absorber for disposal via a tail gas disposal system. The reduced catalyst solution returns to the oxidizer, where sparged air reoxidizes the catalyst solution. The catalyst solution is then returned to the absorber. Sulfur is concentrated in the bottom of the oxidizer and sent to a sulfur filter, which produces the solid sulfur filter cake.

The other oxidation-reduction processes are not included for further consideration for the following reasons:

- Shell's Sulferox is effectively a more concentrated form of the LO-CAT® solution, but with resulting operational issues that makes it less widely used.
- Stretford has significantly declined in popularity due to environmental concerns due to the heavy metal vanadium used in the process.
- The Paques Biological Process has capital intensity similar to LO-CAT®, but with much less operational history, using sodium hydroxide and a bioreactor in the process to generate sulfur cake instead of the LO-CAT® approach using aqueous iron catalyst and air.

There are other units designed for refinery-like facilities to remove additional sulfur from the CBA stream. These include the Superclaus¹³, Euroclaus¹⁴ and others. For purposes of this analysis, however, it was decided not to attempt a specific cost analysis for each process mentioned above. It is more reasonable to pick one of the methods described above and conduct an analysis on that process.¹⁵ It seems more than reasonable to presume that the cost of one of these processes is within the range of what might be expected for any single process. Additionally, cost estimates for these other processes is not readily available. For example, there is no recent published data for the SCOT, Superclaus or Euroclaus. Additionally, cost data is very vague or not available for many of the other units as well.

It was decided to use the LO-CAT® process as a surrogate for any and all of the oxidation or reduction options discussed above. Hess has received cost estimates from a proprietary vendor, Merichem, that provided some of the capital, indirect, and operation

¹² MeriChem reports 200+ installations. <http://www.merichem.com/gas/upstream/natural-gas/lo-cat>

¹³ Information regarding the Superclaus may be found here:

http://www.digitalrefining.com/literature/1000817,Sulphur_Recovery_SUPERCLAUS___Process.html#.W-TGFPZFzDI

¹⁴ Information regarding the Euroclaus may be found here.

http://www.digitalrefining.com/literature/1000580,Sulfur_recovery___EUROCLAUS___process.html#.W-TFnfZFzDI

¹⁵ This approach is discussed in the EPA Guidance. (See footnote 9).

costs associated with the installation and operation of the system specifically at the Tioga facility. The removal efficiency among all the units, including the LO-CAT®, are similar. They all range in sulfur removal from about 80 to 90% above the current operating system (98+%). Should the results of the LO-CAT® (as a representative of oxidation or reduction option) prove favorable, then a more detailed review of some of the options would have been useful.

Flue Gas Desulfurization (FGD)

The second class of sulfur dioxide scrubbing for consideration is the traditional Flue Gas Desulfurization (FGD) unit. As noted earlier, this is the typical sulfur dioxide control system found in most coal and oil-fired electrical generation systems across the U.S. The FGD unit may be configured as a wet, semi-dry, or dry scrubber system. In all cases an alkaline compound (typically CaCO_3 or CaO) is used to react with SO_2 (an acidic gas) to form a compound such as CaSO_3 . The CaSO_3 (and its related compounds) are then removed via a particulate control device such as a baghouse. EPA estimates FGD units' reduction emissions in the range of 50% to 98% where typically wet scrubbers achieve the highest control potential.¹⁶

While this may seem attractive, the FGD scrubbers have significant *a priori* disadvantages for this application. Among them include:

- (a) In order to operate an FGD system, it is necessary to have a significant amount of (solid) material handling equipment on site. This would also include a large surface area to store, move and otherwise handle the reagent and spent-reagent material. This equipment and space might typically be available and designed in an FGD installation such as a coal-fired electrical generation station which handles materials (coal, e.g.) on routine basis. For this gas processing facility, however, none of the required space nor handling equipment is readily available. This would require a significant redesign of the facility in both layout and surface disturbance.
- (b) FGD systems require a particulate control device to remove the alkaline scrubbing agent (CaCO_3 , Ca(OH)_2 , CaO , ...). In a typical power plant facility, a control device to remove particulate would be required regardless of the SO_2 scrubber. For this application, however, no such device is installed nor necessary as particulate emissions from amine sweetening units (with Claus sulfur recovery) is nearly non-existent.

Thus, in order to install and operate an FGD for this facility, not only is an FGD itself necessary, but a complete particulate removal system will be required as well (typically a fabric filter). Thus, the FGD will add a new

¹⁶ EPA Air Pollution Control Technology Fact Sheet – Flue Gas Desulfurization:
<https://www3.epa.gov/ttn/catc1/dir1/ffdg.pdf> *

particulate emissions source at this facility; offsetting some of the reduction achieved by the sulfur-removing FGD system.

- (c) An FGD system, regardless of the type, will require disposal of the spent reagent. Since space is limited at this site, the disposal will most likely take place at a “new” landfill. Thus, in addition to the cost necessary for the FGD, a suitable landfill site would need to be identified and a permit would need to be obtained. This would be a significant undertaking and not especially productive given other non-FGD processes are available.
- (d) The non-FGD processes described earlier are more efficient at reducing sulfur compounds from entering the atmosphere than FGD. The control efficiencies for FGD would likely peak at about 80 to 90% (due to low concentration streams). Non-FGD units are expected to be significantly better.
- (e) For wet scrubber FGD, a complete water system, including disposal, would be required. This is clearly unnecessary given other alternatives and the potential environmental consequences.
- (f) To our knowledge, no FGD system has been installed at any gas processing facility such as the Tioga plant. This fact makes it clear that an FGD system is not a viable option for consideration.
- (g) Finally, it is noted that the WRAP 2009 4-Factor analysis did not itself address nor consider FGD as an available technology. There was no discussion or cost estimates for this control technology.

For all of the reasons above, it was decided to not pursue the FGD option further and it was dropped from analyses that follow.

Acid Gas Disposal (AGD) Injection Well

Another theoretical control option is acid gas disposal (AGD) for the removal of sulfur dioxide and additional waste stream pollutants. This alternative was suggested by the agency as an item for consideration. AGD disposes of the SRU waste gas stream by compressing and injecting the acid gas into a suitable reservoir through an injection well. The control could dispose of the waste stream directly from the SRU.

The gas would be compressed through five stages (engines) of compression to achieve the appropriate pressure for injection into a reservoir. A gas dehydration unit would be required between compression stages four and five to remove water from the acid gas prior to injection. This step reduces hydrate and corrosion risks since water in the presence of high-pressure acid gas would prevent the use of normal metallic equipment and would result in significantly increased costs for the disposal of pipeline and well material. Compression would be achieved by electric drivers.

It has not been established at this early stage whether this option is technically feasible within the meaning of the 4-Factor (via BART) analysis. It is true that this technology has been used in some limited cases and thus it is 'possible' to apply. However, this technology is applied much differently than a typical pollution control technology. Typically, a particular control device is engineered, purchased and then installed on site. AGD is not that case. A key feature is to remove the gas many miles away and dispose of the gas in an unknown location. All of this assumes that it would be 'feasible' to purchase or lease land that Hess does not own and install or purchase a well for which no permit has been obtained and no location identified. Thus it is a folly to suggest this option is technically feasible at this time. It is not known if any disposal well might be appropriate or available in which multiple miles of right-of-way are required through property not yet identified or if the land owner would, in fact, provide permission and at a cost not yet determined. Nonetheless and at the request of the agency, a modest analysis as attempted. Hess does not acquiesce that this option is feasible.

AGD would require the construction of a pipeline and installation of an injection well into an effective formation. Pipeline and injection well tubing size were estimated by Hess along with associated costs for this analysis. Capital cost of compression and dehydration equipment are provided by proprietary vendor data. The project assumes that the compression system would be installed at the Tioga Gas Plant and the high-pressure acid gas would be exported via a 5-mile (initial estimate) pipeline to a new injection well. The assumed formation for injection was the Dakota formation, an aquifer currently used for water disposal from Tioga Gas Plant.

Acid gas injection has, from time to time, been used in North Dakota and has been used before to replace SRU units. However; confirmation of an acceptable injection zone and well location would require significant evaluation, no yet achieved, to understand the risks associated with the process (i.e., sufficient pressure/capacity/seal of a formation, integrity of the casing of nearby wells, and proximity of the Tioga community). In addition, the time to complete the required subsurface work and obtain the required permits for the AGD operation would make this a multi-year endeavor even if the option were feasible.¹⁷

Amine Gas Sweetening Unit (NOx)

The amine gas sweetening unit at the Hess Tioga Gas Plant facility contains no NOx post-control technologies; nor are any needed. NOx emissions from these units are typically very small, negating the need for post controls. Hess had suggested to NDDH that it was not necessary to conduct a 4-Factor analysis for this pollutant/unit. It was later discovered that a published emission factor was available for this unit.¹⁸ Despite a low baseline emission rate for this unit (< 50 tons/year) an NOx analysis proceeded.

¹⁷ The vendor estimates a 3-year delivery time for the basic package.

¹⁸ Emission Factor = 0.1 lb/10⁶ BTU (AP-42, Table 8.13-2, April 2015)

A review of the literature indicates that the only practical technology that might be applied to this unit would be Selective Catalytic Reduction (SCR). SCR technology and its requirements and limitations are explained in detail below in the Compressor Engines section. For the sake of brevity, it will not be repeated here. For purposes of our analysis, however, it has been assumed that such a technology might achieve between 70% and 90% reduction in actual emissions.¹⁹ (The actual NO_x concentration in the steam is low, thus the anticipated percentage reduction would be modest at best).

Although a cost analysis has been conducted for this technology, it is not a foregone conclusion that such an application of SCR would be useful for Round 2. The emission reduction is small from a mass point of view. In addition, we are not aware that SCR has ever been applied at an amine unit anywhere in the US or elsewhere.

Compressor Engines (NO_x)

The gas-fired engines at the Tioga facility drive integral compressors that boost the inlet field gas pressure for processing. The engines are fueled by a portion of the gas stream (pipeline quality fuel gas) produced by the plant. The exhaust gases from each compressor engine are released to the atmosphere through individual stacks.

The seven Clark Engines that have been identified by NDDH are large integral engines; i.e. the engines themselves and the compression structure are constructed as a single unit. Thus, replacement of these engines would be extraordinarily expensive and difficult as both the compression and engine would need to be replaced. Regardless, there are five 1,950 horsepower (hp) engines and two 2,250 hp engines. The two 2,250 hp engines were modified in 2004 by adding turbocharging systems and other means to lower emissions. The emissions from these two engines are about 75% less than the other engines and as such were not subject to additional analyses. The remaining five engines have not been substantively updated since they were installed in the 1950's although they have been maintained in good working order.

Three control options were assessed for the five 1,950 hp Clark Engines: Low Emission Controls (LEC); Select Catalytic Reduction (SCR) and converting engines from gas to electric power.

i) Low Emission Controls (LEC)

LEC application includes various upgrades, modifications, and engine tuning improvements. These typically include a combination of turbocharging [increases air-to-fuel (AFR) ratio], intercooling, enhanced mixing (high pressure fuel injection) and an

¹⁹ This is the range provided by the EPA Air Pollution Control Technology Fact Sheet for SCR: <https://www3.epa.gov/ttn/catc1/dir1/fscr.pdf>

increase in ignition energy.²⁰ LEC is the preferred approach to reduce lean burn engine NOx emissions when compared to alternative options such as SCR.²¹

LEC modifications provide additional air to a controlled engine which, as a result, reduces maximum combustion temperature and minimizes NOx formation. Excess air may hinder combustion of the air-to-fuel ratio in the cylinder, so a high energy ignition source is generally required for engines equipped with LEC. Pre-chamber combustions systems are generally used to aid in combustion, however the power operating range may decrease on two-stroke cycle engines as a result of an LEC conversion. The term “LEC” is often used broadly to describe a number of technology approaches that can be used depending on the engine and NOx emission limit. Normally, multiple LEC related technologies may be required. Therefore, LEC system modifications assessed for the 5 Hess compressor engines were assumed to be on the high end of any given range of costs.

The reduction in NOx emission rates expected from the application of LEC is roughly 70% to 90% (The same reduction may be expected for SCR). For purposes of this 4-Factor analysis and as a matter of consistency among the engines and control technologies (LEC vs SCR), it was presumed that each technology can achieve a controlled emission rate of 1 g/bhp-hr. This emission rate is about the same as a 90% reduction depending on the specific engine and technology. In addition, 1 g/bhp-hr is the emission rate applicable to most new internal combustion engines.²² Since LEC would be applied to a set of older existing engines, the applied emission rate is conservatively low. The cost of compliance is assessed for LEC application to each of the five 1,950 hp Clark engines.

ii) Select Catalytic Reduction (SCR)

SCR is an exhaust control that could be applied to lean combustion engines which reduces NOx emissions by reacting NOx with ammonia or urea over a catalyst. Ammonia or urea is injected into the stream and requires a precise feed-rate based on the NOx concentration and the NO/NO₂ ratio of the NOx. This feed rate, coupled with a narrow temperature range, is critical. If the ammonia feed rate is too low, then the targeted reduction in NOx is not achieved; thus, failing in the agency’s intent to improve regional visibility. If the ammonia rate is too high, then free ammonia is released. The ammonia will itself react in the atmosphere to form compounds such as ammonium sulfate(s) and ammonium nitrate(s). Both compounds are the primary ‘culprit’ that has led to the already observed regional haze concern. Thus, an improper feed rate will lead to a worsening of regional haze rather than making an improvement.

²⁰ “Potential Impacts of the Ozone and Particulate Matter NAAQS on Retrofit NOx Control for Natural Gas Transmission and Storage Compressor Drivers,” Interstate Natural Gas Association of America (INGAA), Report No. 2016-6, December 2017. <https://www.ingaa.org/File.aspx?id=33789>

²¹ “Availability and Limitations of NOx Emission Control Resources for Natural Gas-Fired Reciprocating Engine Prime Movers Used in the Interstate Natural Gas Transmission Industry.” INGAA Foundation. July 2014. <https://www.ingaa.org/Foundation/FDNreports/NOx.aspx>

²² 40 CFR 60, Subpart JJJJ, Table 1.

The process works by ammonia (the reagent) reacting with NO_x on a catalyst bed to form water and N₂. The reaction is characterized as follows:

While SCR has enjoyed a fairly wide applicability in power generation sources, its application to U.S. gas transmission sources has been very limited per INGAA 2014. That analysis details a number of the difficulties of applying SCR to gas transmission engines. These include:

- a) There are numerous technical concerns about SCR's application to compressor engines. Among them are exhaust temperature requirements, reagent control, and the treatment of potential variations in the reciprocating engine exhaust NO/NO₂ ratio.
- b) SCR has been more commonly applied to larger utility scale turbines and boilers and rarely used in compressor engines such as the Tioga facility.
- c) The use of SCR is most effective when operating in the exhaust temperature range of 480 to 800°F. The typical exhaust temperature range for some lean burn engines may present challenges because the minimum operating temperature of the catalyst is dependent on the composition of the exhaust gases and the type of catalyst materials used.
- d) Engines that have variable power loads, such as the case here, require more sophisticated controls to inject the proper amount of reagent, and it is not evident that robust control schemes have been developed for transmission applications.
- e) The installation of a continuous emissions monitor could be required to effectively control the amount of reagent necessary to achieve the desired NO_x emission rate.
- f) SCR catalytic elements can be contaminated by byproducts of combustion (such as oil ash) and more importantly here; engine oil carryover. Cleaning and replacement is required on a periodic basis, and extra management is required to ensure adequate inventories of reagent are maintained.

While EPA claims that SCR is a technology applicable to compressor engines²³ SCR has, in fact, rarely been used in the natural gas transmission and related industry.²⁴ This does provide strong support for its use in this case.

LEC is nearly universally preferred over SCR for existing lean burn engines due to the issues described above. LEC works to prevent NO_x formation while SCR acts to control already formed NO_x in the exhaust stream.

²³ "Air Pollution Control Technology Fact Sheet," SCR, EPA-452/F-03-032.

²⁴ INGAA Foundation, *op. cit.*

iii) Electric Compressors

The third option under (initial) consideration is replacing these natural gas-fired integral (engine + compressor as a single unit) units with an electric powered unit. This possibility has been rejected, however, because such an option does not fall within the suggested EPA Guidance for the identification of alternative controls.²⁵

More specifically, the EPA Draft Guidance document discusses (relying on BART policies) the options that may or should be considered in identifying 4-Factor (via BART) control options. The Draft Guidance contains the following discussion (in identifying technologies outlined by BART and acceptable to the 4-Factor analysis):

*“Potentially applicable retrofit control alternatives can be categorized in three ways. Pollution prevention: use of inherently lower-emitting processes/practices, including the use of control techniques (e.g., low NOx burners) and work practices that prevent emissions and result in lower “production-specific” emissions (note that it is **not our intent to direct States to switch fuel forms, e.g., from coal to gas**), ...”* (emphasis added). EPA Draft Guidance, p 180.²⁶

This comment alone suggests that a fuel switch is not necessarily within the realm of a 4-Factor analysis. Clearly a switch from natural gas to electricity is, in effect, a fuel switch and not the intent of the analysis. The document goes on to provide a more specific discussion:

*“We do **not consider** BART as a requirement to **redesign the source** when considering available control alternatives. For example, where the source subject to BART is a coal-fired electric generator, we do not require the BART analysis to consider building a natural gas-fired electric turbine **although** the turbine may be **inherently less polluting** on a per unit basis.”* (emphasis added). EPA Draft Guidance p. 198.²⁷

Again, the Draft Guidance suggests that one does not need, nor should, consider what amounts to be a redefinition or fundamental change in the underlying facility/unit. If EPA rejects changing an electrical generation plant from coal-fired to a gas-fired turbine as inappropriate, the same logic applies here (gas-fired to electric).

For the reasons above, replacing these gas-fired engines with electric engines has been removed from further consideration.

²⁷ Ibid.

Flares (SO₂ & NO_x)

The acid/wet gas flare (S-101) and high-pressure flare (S-102) operate intermittently at the Hess facility to combust off-spec gas and to address emergency/malfunction events. Both sources are to be assessed for additional NO₂ and SO₂ control. Additional control equipment systems for flare sources are not known or available for a facility whose emission rate is highly variable in both time and quantity. As a result, we are not able to identify any available control technologies for these two specific flares.

Even if a control technology were to present itself, the annual emissions from these two flares would almost certainly yield cost/ton of removal values that are not cost-effective. As evidence, the most recent 2-year average annual emissions for these two flares were:

SO₂

S-101 = 21 t/yr @ 79 hours of operation per year

S-102 = 40 t/yr @ 103 hours of operation per year

NO_x

S-101 = 0.0 t/yr @ 79 hours of operation per year

S-102 = 4.6 t/yr @ 103 hours of operation per year

The low total emissions produced by the flare sources would result in a high cost effectiveness in \$ per ton of emissions reduced since the total cost of implementation would only have the potential to control a minimal quantity of emissions. As a result, no further analyses of potential add-on controls were conducted for this source.

Nonetheless, a Flare Management Plan was also considered as a method for managing efficient operations of S-101 and S-102. The plan design could be similar to flare sources at petroleum refineries subject to 40 CFR Part 60 Subpart Ja which details the Standards of Performance for Petroleum Refineries for which Construction, Reconstruction, or Modification Commenced After May 14, 2007. A Flare Management Plan under subpart Ja requires various information such as: listing all refinery process units and systems connected to the flare; an assessment of whether discharges to the flare can be minimized; and an evaluation of the baseline flow to the flare. However, Hess, in agreement with NDDH, determined a Flare Management Plan would not be a necessary analysis due to the minimal operation of S-101 and S-102. Therefore, no additional analysis of a Flare Management Plan was conducted for these sources and is not included in Section 3.1 Cost of Compliance.

3.1 Factor 1: Cost of Compliance

The cost of compliance estimates the capital cost of purchasing and installing new control equipment along with the annual operation and maintenance (O&M) cost as generally outlined in EPA Draft Guidance. The 2009 WRAP analysis also delineated these cost parameters into the following categories: direct capital cost, indirect capital cost, labor cost, contingency cost, and annual cost. Methodologies given in the EPA Air Pollution Control Cost Manual (Control Cost Manual) are the indicated reference for determining the cost of compliance as directed by the EPA Draft Guidance.²⁸

Costs were expressed in terms of cost-effectiveness in a standardized unit of dollars per ton of actual emissions reduced by the proposed control option. Baseline emissions for the Clark engines and SRU were evaluated to provide emission rates that are representative of the current operations' impact on actual observed visibility (haze) observations at Theodore Roosevelt National Park and the Lostwood Wilderness areas.²⁹ Appendix B contains a brief discussion and rationale for the specific baseline emissions chosen for the analyses in this document.

The capital recovery factor was applied to the control options based on a 20-year equipment life expectancy (25 years for SCR & LEC) applying the prime interest rate (5.5% as of December 19, 2018)³⁰. The cost of compliance is analyzed by source/source group within Table 2 and the following sections.

²⁸ EPA Cost Control Manual (sixth edition): <https://www.epa.gov/economic-and-cost-analysis-air-pollution-regulations/cost-reports-and-guidance-air-pollution#cost%20manual>

²⁹ These are the two closest Mandatory Class I areas that are the subject of a regional haze analysis and form the basis for the need for any potential reduction in emissions from sources in and around North Dakota.

³⁰ <http://www.fedprimerate.com/>

Table 2: Estimated Costs of Control Options for Hess Tioga Gas Plant Sources

Source	Potential Control Option	Pollutant	Estimated Control Efficiency (%)	Potential Emission Reduction (tons/year)	Estimated Capital Cost (\$1000)	Estimated Annual Cost (\$1000/year)	Cost Effectiveness (\$/ton)
Amine Gas Sweetening Unit (SRU)	LO-CAT (or equivalent)	SO ₂	90%	545	32,193	7,199	\$13,217
	SCR	NO ₂	80% ↔ 90%	37	435	273	\$7,414
	Acid Gas Disposal via Injection Well	SO ₂	99%	599	17,788	2,288	\$3,821
Compressor Engines (Mean among 5 engines)	LEC	NO ₂	1 g/bhp-hr ^a	139	9,095	1,205	\$9,589 ^b
	SCR	NO ₂	1 g/bhp-hr ^a	139	745	892	\$7,098 ^c
Flares (2)	N/A	SO ₂	--	--	--	--	--
	N/A	NO ₂	--	--	--	--	--

^a Emission reduction is assumed to achieve approximately 1 gram/bhp-hour.

^b Cost effectiveness per engine ranged from \$16,567 to \$6,890. Individual values are found in Appendix A.

^c Cost effectiveness per engine ranged from \$12,275 to \$5,103. Individual values are found in Appendix A.

^d Capital cost does not include complete analyses in determining appropriate formation and injection scheme. Base-level research costs are accounted for however these costs could greatly vary in scale depending upon suitable geology, formation availability, and well and pipeline feasibility. While annual cost effectiveness appears favorable due to the 99% emissions reduction, the total capital cost is substantial and could likely exceed these early estimates.

3.1.1. Amine Gas Sweetening Unit

LO-CAT® (SO₂)

The cost estimate of a LO-CAT® unit includes the capital cost of constructing the system which comprises the absorber, oxidizer, and filtrate systems. Additionally, the system will require an enclosure because the sulfur forms a solid filter cake that is moist. This creates freezing risks in the winter that necessitates a predominately indoor operation. Capital costs were provided as proprietary information from the vendor; Merichem.³¹ Direct and indirect costs are evaluated using the EPA Control Cost Manual. Indirect costs include engineering design, permitting, construction and field expenses, contractor fees, start-up, performance testing, and contingencies. Operational costs are evaluated primarily from vendor data and other standard techniques. Operating chemical consumption costs are based on system requirements using Merichem proprietary chemicals and utilities. Estimated costs are detailed in Appendix A. Design, construction, and operation of a LO-CAT® system is projected to cost approximately \$13,217 per ton of SO₂ removed.

SCR (NO_x)

To complete the analysis, a cost-effectiveness investigation was conducted for NO_x. As noted earlier, the emission rate at this source is small and has, no doubt, an insignificant impact on regional haze. Regardless, a cost analysis was completed for SCR. Using the capital cost estimates found in EPA's Air Pollution Control Technology Fact Sheet, SCR, EPA-452/F-03-032,³² Table 1a, the cost effectiveness for controlling NO_x was estimated at \$7,414 per ton removed.³³ This value is outside the normal cost effectiveness range and thus is removed from further consideration.

Acid Gas Disposal (SO₂)

The cost estimate of an AGD system includes the capital cost of constructing a 5-stage compression and acid gas dehydration system, a pipeline to export waste gas, and an injection well into a qualifying reservoir. Indirect costs are substantive due to the overall development of an AGD system which include engineering design of the compression and dehydration system, pipeline, well, and stormwater management system; soil site characterization; geological surveying for reservoir characterization; environmental, cultural, and wetland delineation for an environmental assessment; site surveying; field inspections; industrial commission permitting; and contractor and equipment transportation fees. Capital costs for the compression and dehydration equipment are derived from proprietary vendor data that does not include EXW cost such as loading, freight, installation, etc. Direct and indirect costs for freight, engineering, construction, etc. are calculated using guidance and factors provided in the EPA Air Pollution Control Cost Manual. Installation and equipment cost of the pipeline and injection well are estimated by Hess as these activities directly involve their product/business lines. Pipeline

³¹ General information regarding Merichem and LO-CAT may be found: <http://www.merichem.com/gas>. The specific costs provided are considered Business Confidential by the vendor and are thus not provided in this document.

³² <https://www3.epa.gov/ttnatcat1/dir1/fscr.pdf>

³³ Details of the calculation are found in Appendix A.

installation is calculated based on \$125,000 per foot-diameter mile of pipeline and the installation well cost is estimated at 10,000 ft true vertical depth with 2-7/8" tubing.

The total capital investment of an AGD system is estimated at approximately \$17,800,000 not including operating expenses or many other factors for which there is not enough information at this early stage. Based on this incomplete data, the cost effectiveness was estimated as \$3,821 per ton removed (SO₂). If a more detailed analysis is warranted, the cost will, no doubt, rise substantially. This control option will require significant further evaluation to understand surface and subsurface risks (i.e., formation pressure-volume-seal, integrity of casing of nearby wells, proximity of the Tioga community, etc.) that are difficult to estimate at this early juncture. As a result, the cost of compliance is expected to be larger than this early estimate. Cost calculations for AGD are detailed in Appendix A.

3.1.2. Compressor Engines

The Clark Engines analysis included estimated costs for updating each of the five 1,950 hp with either LEC or SCR.

LEC (NO_x)

The LEC analysis is based on various upgrades and changes to the 5 engines. At Hess' request, and unrelated to this 4-Factor project, Siemens³⁴ provided a cost estimate for a LEC upgrade to a Clark engines. The scope of work and cost estimate is Siemens proprietary information. An upgrade to LEC consists of the following per Siemens:

- Hardware and engineering costs for replacing the existing cooling systems with water pump systems to eliminate boil-off cooling.
- Field service, repairs, and parts replacement for zero-hour overhaul.
- Hardware, installation, and commissioning of a HPfi fuel injection upgrade that needs to include:
 - A single "Balance of Plant" engineering and hardware support for multiple engine revamps.
 - Hardware, installation, and start-up of the HPfi equipment.

Using this information, LEC direct capital costs are approximately \$4 million per engine. This cost coupled with the various emission rates for each of the five engines yielded a cost effectiveness ranging from \$16,567 to \$6,890 per ton of NO_x removed. This equates to an average cost effectiveness among the 5 engines of \$7,577.

It is theoretically possible to apply LEC to a subset of engines (e.g., 2 of the 5 engines). Doing so would yield a slightly lower cost effectiveness because one of the capital expenditures quoted by the vendor (balance of plant) need only be done a single time regardless of how many engines are retrofitted at the instant in time. This cost savings

³⁴ <https://new.siemens.com/us/en.html>

assumes, of course, that all the retrofitted engines would be completed at the same time. That might prove problematic for plant operations as it is always imperative to have the necessary compression in the plant.

Regardless, it was instructive to briefly review the cost effectiveness of a retrofit for 2 (as an example) of the engines. Choosing the 2 lowest cost engines (\$/ton) would result as follows:

Engine C-1C:		
Stand Alone = \$6,890/ton	With 2 Engines = \$6,235	
Engine C-1E:		
Stand Alone = \$7,050/ton	With 2 Engine = \$6,296	

While a savings would be recognized, the degree of improvement is not notable nor would likely change a final 4-Factor conclusion (assuming there is any perceptible improvement in regional haze impact from any of the control options).

SCR (NO_x)

The capital costs for SCR, if one were to assume this was an 'achievable technology' for this application, are varied. There are a number of published cost estimates for typical coal- oil- and gas-fired medium to large sized boilers. The same cannot be said for a retrofit of a natural gas-fired compressor engine/compressor.

In addition, the cost of retrofit SCR is much higher than an original installation which would apply to this analysis. SCR systems used to retrofit an existing unit increase costs up to about 30%.³⁵ O&M costs may also be substantially dependent on reagent usage, catalyst replacement, and increased electrical usage. The average (all 5 engines) cost effectiveness of SCR was \$7,098 per ton removed. Individual engines ranged from \$12,275 to \$5,103. This cost effectiveness range coupled with multiple technical difficulties and its non-use in this general application does not make it an attractive Round 2 candidate.

The derivation of the capital cost figures, emission rates and other general information may be found in the appropriate tables in Appendix A.

³⁵ EPA Air Pollution Control Technology Fact Sheet – SCR: <https://www3.epa.gov/ttn/catc1/dir1/fscr.pdf>

3.2 Factor 2: Time Necessary for Compliance

Per the EPA Draft Guidance, the provisions for this factor within the BART guidelines should be utilized to estimate time necessary for compliance. Additionally, the best guide to determine time necessary for compliance is prior experience with the planning and installation of new emission controls. Source-specific factors should be considered as well.

EPA has estimated that it takes approximately 30 months to design, permit, build, and install a typical SO₂ scrubbing control unit for a single source. No specific data was located as it regards the LO-CAT unit (or its equivalent). Using the EPA estimate as a guide, their analysis also determined that 12-months is additionally required for a project including the installation of control equipment on multiple sources. Another 12 months may be required for staging the installation process across the multiple sources. Finally, it is generally recognized that facilities may require a 1 year (or more) for the procurement of project funding.

As a result, the time necessary for compliance for the LO-CAT unit is estimated at between four and five years. This time period accounts for about one year of capital acquisition; two to three years for designing, permitting, constructing, and installing the control equipment; and one year for shakedown and commissioning.

A longer timeline would also be expected for the LEC conversion for the five engines discussed in this report. The installation, tuning and integration would need to be executed in a sequential fashion in order to keep the facility in operation during this time. This will stretch the 'time necessary for compliance.' No specific time-line is offered at the time of this report. However, it would be reasonable to suggest that the time needed would be 5 years (one per year) as a minimum and perhaps as long as 7 depending on commissioning and plant operations.

Although no specific data was found, it would be reasonable to assume that a five-year period would also be appropriate for the installation of SCR in lieu of LEC being required. Finally, it was further reasoned that this five-year period serves as an estimate for the time necessary for installation of an SCR unit on the Amine Sweetening Unit, although its (and others) installation is not justified for cost effectiveness reasons.

It is likely that an even longer timeframe would be required for AGD installation. To begin, a likely vendor/supplier of the compressor engines and acid gas dehydration equipment estimated a 3-year delivery for that equipment alone. Additionally, AGD requires initial land surveying and additional permitting. Substantial surveying would be required to determine the appropriate location for an injection well for both surface and subsurface purposes. Land acquisition could be required for the location of the injection well which would require surface title research to determine a database of landowners whom would allow AGD injection within their property. Subsurface research would also be required to verify mineral title requirements and geotechnical evaluations that ensure the proposed

formation has appropriate pressure limitations, volume, and seal. Additionally, a pipeline would need to be designed and permitted to connect the Tioga Gas Plant to a proposed injection well location posing additional challenges. These evaluations and logistics could add considerable time and unforeseen expense to an AGD project.

3.3 Factor 3: Energy and Non-Air Quality Environmental Impacts of Compliance

The provisions of the BART Guidelines are recommended for assessing both energy and non-environmental impacts. The EPA Draft Guidance states that an energy impacts assessment should be considered in terms of kilowatt-hours or mass of fuels used accounting for direct energy consumption cause by control implementation. Indirect energy inputs to produce the raw materials for construction of equipment should be excluded from the analysis. The Control Cost Manual is the preferred reference and provides advice on estimating energy requirements. Non-air environmental may include the cost associated with solid waste disposal, wastewater discharge, acid or nitrogen deposition, and climate impacts.

3.3.1. Amine Gas Sweetening Unit

LO-CAT® or Equivalent.

Per Merichem (proprietary), a LO-CAT system does not use any toxic chemicals and does not produce any hazardous waste byproducts. It requires a reasonable amount of catalyst however it is continuously regenerated in the process. Spent catalyst may require disposal though the implications of disposal of this waste stream has not been analyzed at this time since the cost effectiveness does not make its use a practical alternative.

There is also an energy cost associated with this added level of emission controls. It has been estimated that this level of technology would require about 610 kW-hr of use.³⁶

AGD Injection Well.

A new waste stream from compression and dehydrator unit will be generated from this control method. AGD via an injection well is the disposal of pipeline and well tubulars in the event of water entering the system due to dehydrator breakdown/failure. Acid gas in the presence of water creates hydrate and corrosion risk which significantly increases the proper disposal of pipeline and well material. Additional environmental risks from the construction of the pipeline and injection well will need to be mitigated through various permitting and Environmental Assessment processes.

There is also a substantial electrical input required to operate the 5-stages of compression. The compression units are estimated to require approximately 950 kW-hr of energy.³⁷

³⁶ Proprietary information provided by Merichem.

³⁷ Proprietary information provided by compression and dehydration vendor.

3.3.2. Compressor Engines

SCR.

SCR control systems require the use of aqueous ammonia, anhydrous ammonia, or urea-to-ammonia reagents for the reduction reaction. Systems that use urea produce aqueous ammonia onsite. Anhydrous ammonia is nearly pure ammonia gas and must be transported and stored under pressure. Anhydrous ammonia is classified as a hazardous material which often requires special permits as well as additional procedures for transportation, handling and storage. Systems using aqueous ammonia transport and store the reagent concentration in water, generally $\approx 28\%$ ammonia to water.³⁸ While aqueous ammonia can be safer to transport and store, the diluted ammonia concentration requires more storage capacity than anhydrous ammonia and requires shipping costs for the water solvent in the solution. Hess would be required to account for additional chemical storage, protection, and permitting with the additional reagent solution stored on site.

Additionally, SCR systems utilize catalysts to aid in NO_x control. The catalysts are generally composed of active metals or ceramics with a highly porous structure. Activated sites are located within the pores of the catalyst and these sites have an acid group on the end of the compound structure where the catalytic reduction reaction occurs. The catalyst material reactivates via rehydration or oxidation after the reduction reaction occurs. This is a limited process, however, and over time the catalyst activity decreases, requiring replacement, washing/cleaning, rejuvenation, or regeneration of the catalyst. Catalyst storage, transport, and disposal must then be accounted for in the SCR control viability analysis.

An estimate was made of the aqueous ammonia feed rate necessary for the facility. It is estimated that with all 5 engines in operation, a feed rate of about 15 gallons per hour per engine would be necessary.³⁹ To handle this much material would require a large storage tank ($\approx 18,000$ gallons for all engines) to have a 10-day supply. The storage or use of this quantity triggers the requirements of the accidental release program found in 40 CFR 68.⁴⁰ Depending upon specifics, a detailed amendment to the risk management plan (RMP) must be developed and implemented under this program. This only adds another layer of regulatory reporting along with an unnecessary risk by itself. The fact that such a plan would be required dampens its attractiveness for consideration.

³⁸ EPA Cost Control Manual (sixth edition): <https://www.epa.gov/economic-and-cost-analysis-air-pollution-regulations/cost-reports-and-guidance-air-pollution#cost%20manual>

³⁹ See general calculations and data found in Appendix A (from EPA Cost Control Manual).

⁴⁰ The program is triggered for aqueous ammonia use or storage greater than 20,000 pounds. The quantities described exceed this value.

LEC.

The LEC technology does not require the handling or storage of hazardous materials as is the case for SCR. The LEC technology does not require, on its face, changes in pressure drop across any system that could create an energy demand penalty.

3.4 Factor 4: Remaining Useful Life

The Hess Tioga Gas Plant remaining useful/service life is not specific at this time. As discussed in the 2009 WRAP Analysis, the service life of these emission sources at industrial facilities are difficult to estimate.

The startup dates for these units were:

Amine Sweetening Unit:	1991
Compressor Engines (5):	1954
Flares:	n/a

Regardless of the ability to select a particular time, the service life of the analyzed control technologies was estimated to be 20 years (25 years for LEC & SCR). The 20-year figure was used to amortize the capital costs of the add-on and modified (LEC and SCR for the compressor engines) emission controls at the recommendation of NDDH. Given the historical perspective, it is reasonable to conclude that the remaining life of the facility (Sweetening Unit and Engines) itself is expected to exceed the life of the control equipment.

The capital cost of the control equipment would need to be amortized over a shorter period if the remaining life of an emission source is less than the projected life of the new control equipment. Since this was not the case, the remaining equipment life of the facility is expected to equal or exceed the life of the analyzed technology options.

4.0 CONCLUSIONS AND RECOMMENDED SELECTION

A 4-Factor analysis has been conducted for the Hess Tioga facility. The analysis was conducted to meet the requirements of “Round 2” to develop of a State Implementation Plan (SIP) to address Regional Haze. Regional haze requirements and goals are found in Section 169A of the Federal Clean Air Act and codified in 40 CFR 51.308(d)(1). To implement the requirement, the North Dakota Department of Health (NDDH) submitted a letter to Hess dated May 18, 2018, seeking such an analysis.

The 4 factors to be analyzed based on the NDDH letter and the regional haze rule were:

- Factor 1. Cost of compliance
- Factor 2. Time necessary for compliance
- Factor 3. Energy and non-air quality environmental impacts of compliance
- Factor 4. Remaining useful life of any existing source subject to such requirements

NDDH then requested a 4-Factor analysis for SO₂ and NO_x for the following source groups:

- 1. Amine Gas Sweetening Unit (S-302)
- 2. Clark Compressor Engines (C1A – C1G)
- 3. Flares (S-101 and S-102)

The emitting units were analyzed for these factors in general accordance with EPA's Draft Guidance.⁴¹ The details of those results were presented in prior sections of this report.

⁴¹ *Draft Guidance on Progress Tracking Metrics, Long-term Strategies, Reasonable Progress Goals and Other Requirements for Regional Haze State Implementation Plans for the Second Implementation Period*,” EPA, EPA-457/P-16-001, July 2016.
https://www.epa.gov/sites/production/files/2016-07/documents/draft_regional_haze_guidance_july_2016.pdf

Amine Gas Sweetening Units.

SO₂

Three control technologies were considered for this unit-pollutant combination: Oxidation or Reduction Control (LO-CAT), Flue-gas desulfurization (FGD), and Acid gas disposal (AGD) via injection well. The LO-CAT technology (or its equivalent) essentially converts H₂S in the acid gas to solid elemental sulfur using an aqueous solution of iron as catalyst. The FGD system, typically found in a coal-fired power plant, treats exhaust gas with an alkaline reagent (usually CaO or CaCO₃) to remove SO₂. The spent reagent (CaSO₃ or CaSO₄) is then collected in a fabric filter unit in which the collected dust must be treated in a licensed landfill. AGD requires substantial design and preliminary surveying to determine the appropriate geological formation to install an injection well, pipeline, and compression-dehydration system.

It is concluded that the FGD system is not practical nor appropriate for this application. Those reasons include (but not limited to):

- A new emitting source (particulate) would be added to the plant offsetting some of the benefits of a reduction in SO₂;
- A new disposal system would be required to treat the spent reagent,
- FGD has never, to our knowledge, been used in treating SO₂ emissions from any gas processing facility; and
- The prior (2009) 4-Factor analysis for this facility did not identify nor consider FGD as a viable technology.

The LO-CAT® technology (or its equivalent) was analyzed. While the technology may be applied to a facility like the Tioga plant, it was rejected due to its high cost effectiveness (≈ \$13,217/ton).

AGD is also not practical nor appropriate due to the unknown costs associated with determining surface and subsurface risks prior to the development of the pipeline and injection well. Additionally, the energy and environmental impacts add to the impracticality of this control option due to the additional electricity required to drive compression (nearly 1 megawatt).

NO_x

Although the emission rate of NO_x from the unit is very low, an analysis for this unit was conducted for thoroughness. The technology identified most probable for this unit is Selective Catalytic Reduction (SCR). SCR was rejected as inappropriate for numerous reasons including its rare use in integral engine-compressors and even more notably SCR's high cost (≈ \$7,414/ton). Therefore, SCR is not a candidate for Round 2 emission reductions.

Compressor Engines.

NO_x

There were two control technologies identified for reducing NO_x from these units: SCR and Low Emission Control (LEC).

LEC is a system of upgrades, modifications and tuning of the engines to achieve a lower emission rate. LEC could, theoretically, be applied to each of the 5 compressor engines subject to this analysis.

The cost effectiveness of this technology was excessive. The average cost effectiveness was \$9,589/ton for each of the 5 engines. The engine-by-engine cost effectiveness ranged from roughly \$6,890 to as high as \$16,567 depending on the engine. Since these values are considered excessive, LEC has been removed from consideration for Round 2.

SCR was also analyzed as a potential control technology. However, SCR is rarely, if ever, used for this type of application. Evidence of that stems from several reports. One recent study (2014) makes the following comment: “*To date, SCR application to U.S. gas transmission sources has been very limited, and SCR has not been applied to **an existing integral engine** (emphasis added).*”⁴² The 5 engines at the Tioga facility are existing integral engines as described in the report. In addition, an even more recent report failed to consider SCR a noteworthy technology for reducing NO_x emissions from transmission and storage compressors as a means of achieving the ambient NO_x standards.⁴³

Additionally, SCR carries the burden of handling and storing either anhydrous ammonia (NH₃) or aqueous ammonia (NH₄OH). This would require new equipment in which to transport and handle this material. In both cases, the storage quantities necessary will trigger the need for a Risk Management Plan (RMP) required by the Accidental Release program (40 CFR 68) in order to address the potential of a spill or release that could have public health implications. The addition of this equipment constitutes an unnecessary risk for the purpose of regional haze.

In addition to the burdens described, the efficacy of the control technology is at issue. For SCR to work effectively, a precise ammonia feed rate

⁴² “*Availability and Limitations of NO_x Emission Control Resources for Natural Gas-Fired Reciprocating Engine Prime Movers Used in the Interstate Natural Gas Transmission Industry.*” INGAA Foundation. July 2014, Page 9. <https://www.ingaa.org/Foundation/FDNreports/NOx.aspx>

⁴³ “*Potential Impacts of the Ozone and Particulate Matter NAAQS on Retrofit NO_x Control for Natural Gas Transmission and Storage Compressor Drivers.*” Interstate Natural Gas Association of America (INGAA), Report No. 2016-6, December 2017. <https://www.ingaa.org/File.aspx?id=33789>

coupled with a narrow temperature range are necessary. Both conditions would be difficult to maintain due to varying loads on the compressor engines themselves.

Finally, the cost effectiveness of SCR is, overall, excessive. The average cost effectiveness was \$7,098 for all 5 engines. The engine-by-engine effectiveness ranged from roughly \$5,103 up to \$12,275. Due to these costs, the technical concerns, the need to handle hazardous materials and the nearly universal lack of use of SCR for legacy compressor engines, SCR is rejected for Round 2 purposes.

Flares.

NO_x and SO₂

A review of the literature does not yield any 'available' control technology to control either NO_x or SO₂ emissions from these highly intermittent sources such as the Tioga flares. The flares primarily serve emergency and other upset conditions. For example, each flare operated 0.1% of the time in the past 2 years. Clearly, any control technology, even if it were available, would not have a measurable impact on the regional haze long-term goals. Because no reasonable technology is available, and no measurable regional haze benefit would be realized, it is concluded that there are no technology options available for these sources.

A Flare Management Plan similar to flare sources at petroleum refineries subject to 40 CFR Part 60 Subpart Ja would also not be appropriate due to the minimal flaring events at S-101 and S-102. Therefore, no additional analysis of a Flare Management Plan was conducted for this source.

Following a careful review of the information it is concluded that additional emission controls and limitations for these sources are not necessary to make reasonable progress based on the 4-Factor analysis.

Siemen's Budgetary Proposal

Hess Tioga Facility: Estimate to Revamp/Upgrade Unit 5 (Serial 54040) : C1-E

September, 2018

Item #	Cost	Basis	Discussion
1	\$345,000	Per Engine	Replace existing cooling system to eliminate boil-off and replace water pump system. This includes hardware and engineering only.
2	\$2.5 million	Per Engine	Complete "zero-hour" overhaul. Includes field service, repairs and necessary parts replacement.
3	\$3.7 ↔ \$4.2 million	Per Engine	Provide high pressure fuel injection (HPFI) upgrade implementation. Includes hardware, installation and commissioning.
4	\$2.0 ↔ \$2.5 million	One-time cost	One-time "balance of plant" engineering and hardware to support multiple engine retrofits. Cost is the same regardless of 1 or all 5 engines.

Emissions Inventory: Actual (Average of past 5 years with min & max years removed from the calculation)

Engine	Tons/Year (5-yr mean with min & max removed)
C-1A	91
C-1B	160
C-1C	193
C-1E	189
C-1G	153

APPENDIX B: BASELINE EMISSION RATES

This appendix contains a brief summary of the derivation of emission rates used to define the “Baseline” emissions for this analysis. The 4-Factor analysis requires that a “cost effectiveness” be determined for each (or combination) control option identified as practical or available.

Clark Engines - NOx

The 5 Clark engines, subject to this analysis, are expected to be used less in the future. Part of the reason relates to the nature of the gas field(s) processed and part of the reason is that Hess expects it will slowly switch from the current gas-fired units to electric driven compressor engines. Regardless, baseline emissions for the existing Clark engines were evaluated using the most recent 5 years of data (2014 → 2018). It did not seem necessary to go further back in time since it would be less and less likely to represent a current (or near current) emission rate.

A review of historical data shows that there is a modest degree of variability in emission rates both within and among the engines. There is roughly a 30% difference in NOx emission results (emission factor) for the same engine over several years. The same is true when comparing the 5 engines across a specific testing period. As a result, the baseline emission rate should be established not so much by a particular rate based on NOx itself but on the underlying function of the engines (to avoid setting a value based on random testing variability).

To evaluate the baseline emissions, it is necessary to understand and review the hours of operation for these devices. Recall that the purpose of these engines is to compress gas and move it from one point to the other. Given each of the 5 engines is the same size, each hour of operation represents, more or less, a known or set quantity of compression. Therefore, to determine baseline emissions, it is necessary to establish the baseline hours. From the baseline of hours, one can then determine the NOx emissions rate that is most representative of recent and expected operation (i.e. compression).

The table below provides a summary of the hours of operation for each engine.

Clark Engines: Hours of Operation by Year

Year	C-1A	C-1B	C-1C	C-1E	C-1G	C-1D*	C-1F*	All
2014	2400	4814	5012	5594	5312	7220	4820	35172
2015	6520	7749	5818	7437	7885	10276	10487	56072
2016	3720	6417	6965	6600	5217	8623	9745	47287
2017	528	3506	4258	2070	6240	9994	8210	34806
2018	3136	4437	4647	0	5253	4489	6518	28482

* Note the hours on these units were normalized (upward) to account for the fact that these units have a higher horse power rating and thus compress more gas than the 5 engines of interest.

For interest the same information is shown in the graphic below for the 5 Clark engines.

Clark Engines: Hours of Operation by Year

The data suggests that there may be a downward trend. The R^2 value is 0.36 which roughly indicates that about 36% of the observed data fits the linear model (as a linear least-squares correlation) well. This fits our contention that the engines are used less and less.

A review of the data does not lead to an obvious baseline value. It was hypothesized that perhaps the best non-biased method to use would be to use an average of the results (per engine). On the other hand, the variability of the data is quite large. It ranges from roughly 35,000 hours per year to 16,000; a factor of 2 difference. Upon reflection, a better approach would be to remove the minimum and maximum values from the data set to remove some of the variability. This was the approach taken to determine hours of operation per engine which then leads to the baseline NOx emission rate.

The data above, thusly, indicates that years 2014, 2016 and 2017 were selected. From that information, the following baseline emissions data emerges.

NOx Emissions (tons) – Baseline Years

Year	C-1A	C-1B	C-1C	C-1E	C-1G
2014	85	167	198	230	155
2016	171	215	255	257	150
2017	18	99	127	81	155
Baseline	91	160	193	190	153

Interestingly these values, taken as a whole and as a representation of total gas compression, are quite similar to using the simple average from the 5 years. This confirms that the choice of baseline data is reasonable.

Sulfur Recovery Unit (Amine Sweetening Unit): SO₂ & NO_x

The selection of the baseline year(s) data for the SRU is a simpler task than the Clark engines. A historical review of the hours of operation of this unit reveals a relatively straight flat line as time progresses. Both the year hours and emissions from this unit are shown in the table below covering an 11-year period.

SRU Yearly Hours and Emissions

Year	Hours	Tons SO ₂
2008	8,750	707
2009	8,759	739
2010	8,665	694
2011	8,638	745
2012	8,649	683
2013	7,604	668
2014	6,816	345
2015	8,760	408
2016	8,760	482
2017	8,760	715
2018	8,760	994

The same information is shown in the figure below.

SRU Yearly Hours and Emissions

The table and figure show a very consistent operation from this unit. Nearly every year annual operation approaches 100% utilization with a few minor exceptions. Those years most at odds with the typical year coincide with various operational changes occurring at the unit at that time.

One item of note is an apparent increase in SO₂ from 2014 forward. It should be noted that this increase is not particularly relevant as an indication of a future trend. The reason for the increase relates to the operation of the Claus plant; not the amount of gas processed. For example; below is the amount of produced gas at the plant from 2014:

Gas Processing
(billion ft³)

Year	Received (wet)	Produced	SO ₂ (tons)
2014	39	20	345
2015	71	36	408
2016	62	36	482
2017	64	39	715

Clearly the amount of gas processed at the plant has no distinct correlation with the SO₂ emissions. The reason for the increase in SO₂ during this time period relates to proper operation of the Claus plant itself. The changes in the concentration of H₂S in received gas along with other operational parameters has led Hess to conduct a study of the Claus operation and possible remedies to bring it back to its achievable efficiency. It was this analysis that led to obtaining vendor quote for alternatives such as the LO-CAT® and acid gas injection well.

As was the case with the Clark engines, it was deemed appropriate to remove the maximum and minimum year data from the data set. This results in a 9-year average value which seems reasonable for this 4-Factor analysis. The annual baseline emissions for the SRU are 605 tons/year.⁴⁴

For NO_x emissions, the baseline emissions were calculated using AP-42 values (AP-42, Section 8.13, Table 8.13-2, April 2015). As a matter of convenience only the past 4 years of available data were reviewed since they are based on fuel burned at the unit; not emissions testing. The NO_x emissions from the SRU were calculated as follows:

SRU Yearly Hours and Emissions

Year	Hours	Tons NO _x
2014	6,816	38
2015	8,760	40
2016	8,760	52
2017	8,760	54

Given the smaller sample size, it was decided to include the values from all 4 years yielding a baseline emission rate of 46 tons per year.

⁴⁴ As a side note, the annual emission value is only slightly different with or without removing the min and max year's data.

Re: Regional Haze 4-Factors Analysis
Hess Tioga Gas Plant

Dear Mr. St. Clair:

The North Dakota Department of Health (Department) has conducted an initial review of your four-factors analysis for the Hess Corporation (Hess) – Tioga Gas Plant (TGP) in North Dakota. With respect to the analysis we have the following comments:

1. The expected life of the control equipment selected appears too low: tail-gas scrubbing treatment (SCOT), low-emission combustion (LEC), and selective catalytic reduction (SCR) are each listed in the economic analysis with an expected life of 10 to 15 years.
 - a. A more appropriate life of a SCOT is 20 years.
 - b. A more appropriate life of a LEC is, at a minimum, 20 years. It has already been ~17 years since upgrades were performed on C1D and C1F at the TGP.
 - c. A more appropriate life of a SCR for a natural gas-fired unit is 20-30 years (see EPA's Control Cost Manual, Section 4.2, Chapter 2, p 2-78).

The analysis must be redone using an appropriate expected life. At a minimum, justification of why each value was chosen needs to be included.

2. The 10% interest rate for the Amine/SCOT (Appendix A-3) and the 8.25% interest rate for the Engines (Appendix A-10 through A-21) used in the economic analysis appear to be too high. EPA's Control Cost Manual (Manual) states "When performing cost analysis, it is important to ensure that the correct interest rate is being used. Because this Manual is concerned with estimating private costs, **the correct interest rate to use is the nominal interest rate, which is the rate firms actually face** [emphasis added]". The Manual further states "For input to analysis of rulemakings, assessments of private cost should be prepared using firm-specific nominal interest rates if possible, or the bank prime rate if firm-specific interest rates cannot be estimated or verified." The current bank prime rate is 5.25%. The Department believes an interest rate no higher than 5.25% should be used. Attached to this letter is an email we received from EPA regarding this matter.

The economic analysis must be redone using an appropriate interest rate. At a minimum, justification of why each value was chosen needs to be included.

3. The baseline emission rates for Emission Units C1A, C1B, C1C, C1E, and C1G appear to be too low. While the most recent 2-years of data (2016-2017) were used, this doesn't appear to be representative of past operations or future expected operations. Average utilization was low in 2016-2017 (mainly due to 2017 operations). See tables below for the data the Department has on file regarding recent emissions and utilization, which were derived from hours of operation.

2-year averages Emissions	C1A	C1B	C1C	C1E	C1G	C1D	C1F
2014-15	161.6	230.2	203.4	291.6	181.1	21.9	24.4
2015-16	204.9	254.0	232.4	305.3	178.6	27.2	32.4
2016-17	94.4	156.9	191.2	169.2	152.7	25.1	29.6

Utilization	C1A	C1B	C1C	C1E	C1G	C1D	C1F
2014-15	51%	72%	62%	74%	75%	81%	71%
2015-16	58%	81%	73%	80%	75%	88%	94%
2016-17	24%	57%	64%	49%	65%	87%	84%

Avg. Engine Utilization	A/B/C/E/G	D/F	All engines
2014	53%	56%	54%
2015	81%	96%	85%
2016	66%	85%	71%
2017	38%	85%	51%

Years 2015 and 2016 appear to be more representative of baseline numbers. Justification of the baseline years selected needs to be provided, especially when the baseline is not easily determined.

4. Are there any limitations to refurbishing, rebuilding, or retrofitting two to three of the engines, which have not already been modified (C1A, C1B, C1C, C1E, C1G) and operating them at an increased utilization? This is more consistent with C1D and C1F utilization.
 - a. Future operations could utilize the LEC modified engines first with the non-LEC modified as backup in the event of SSM (i.e. C1A, C1B, C1C, C1D, and C1F would have priority and C1E and C1G would operate as backup). Based on past plant data, this looks like the plant would still have enough inlet capacity to handle daily operations.
5. Documentation must be provided for the cost estimates. Any references, other than EPA's Control Cost Manual, must either be submitted with the analysis or a website address must be provided where the documents can be downloaded. Documentation must also be provided for any scaling done to obtain the cost estimates.
6. The capital cost derivation for a LEC was estimated at \$4 million. The referenced paper used for the cost estimate indicates a **total cost** of \$ 2-4 million. It is indicated the upper

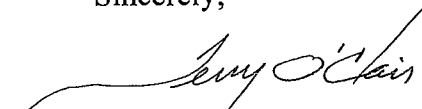

one-third was used to account for older engines. The upper one-third would be \$3.33 million. Also, additional costs for equipment, installation and indirect costs were added. The Department's interpretation is that the referenced **total cost** (\$ 2-4 million) is the "total capital investment" (TCI). Justification for the additional capital costs is required.

7. Acid gas injection must be considered for SO₂ reductions at the SRU.
8. The preparation and implementation of a flare management plan to control emissions from flares must be addressed and included in the analysis.
9. The cost estimate for the SCOT tail gas clean-up system references WRAP's 4-factors analysis for North Dakota from 2009. The \$15 million estimated capital cost in WRAP's report includes purchased equipment, installation costs and indirect capital costs (i.e. Total Capital Investment (TCI) – see page 2-1 of the WRAP report). Hess's SCOT estimate adds additional capital costs, installation and indirect capital costs which are already included in the \$15 million capital cost. The additional capital costs must be eliminated.
10. Note: Historic emissions from S302 appear to be incorrect and overreported from 2008-2015. The Department did not look back farther than 2008 during this review. Emissions data for 2016 and 2017 appear to be correct.

Year	SO ₂ Emissions tpy (reported)	Tail Gas Incinerated MMcf/y	Average H ₂ S mole%	Operating Time hours	SO ₂ Emissions tpy (calculated from inputs)	Reported minus Calculated (per equation in AEIR form)	These are significantly different
2008	1049	2095.48	0.40	8750	707	343	
2009	1102	1825.8	0.48	8759	739	363	
2010	1045	1469.73	0.56	8665	694	351	
2011	1126	1522.95	0.58	8638	745	382	
2012	1022	1350.31	0.60	8649	683	339	
2013	1022	1056.08	0.75	7604	668	354	
2014	515	772.64	0.53	6816	345	170	
2015	614	820.56	0.59	8760	408	206	
2016	481	1100.14	0.52	8760	482	-1	
2017	719	1130.73	0.75	8760	715	4	

The revised analysis should be submitted as soon as possible. If you have any questions, please contact David Stroh or Tom Bachman of my staff at (701) 328-5188.

Sincerely,

Terry L. O'Clair, P.E.
Director
Division of Air Quality

Omaha, NE 68154

Re: Regional Haze
Second Planning Period

Dear Ms. Jensen:

The Department of Health (Department) has begun work on the second planning period (Round 2) State Implementation Plan (SIP) for regional haze. In Round 1 of the regional planning process, the emphasis was on Best Available Retrofit Technology (BART) and making reasonable progress towards the national visibility goal. In Round 2, there are no BART requirements; therefore, we will focus on making reasonable progress. The reasonable progress analysis will be made using the four factors in Section 169A(g)(1) of the Clean Air Act:

The four factors are:

1. The cost of compliance
2. The time necessary to achieve compliance
3. The energy and non-air quality environmental impact of compliance; and
4. The remaining useful life of any existing source subject to such requirements

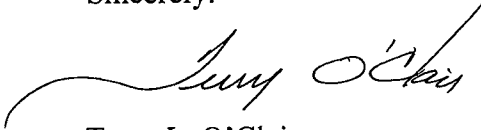

Guidance provided by the U.S. Environmental Protection Agency (Draft Guidance on Progress Tracking Metrics, Long Term Strategies, Reasonable Progress Goals and Other Requirements for Regional Haze State Implementation Plans for the Second Implementation Period at https://www.epa.gov/sites/production/files/2016-07/documents/draft_regional_haze_guidance_july_2016.pdf) indicates the Department must address 80% of the visibility impairment caused by in-state sources. Data from the IMPROVE monitoring sites at Theodore Roosevelt National Park (TRNP) and Lostwood Wilderness Area (LWA) indicate that sulfates and nitrates continue to be the largest contributors to visibility impairment in these areas. The primary precursors of sulfates and nitrates are emissions of sulfur dioxide (SO₂) and nitrogen oxides (NO_x).

Northern Border Pipeline's Compress Station No.4 is a significant source of NO_x and is located very close to a Class I area. Therefore, the Department requests that you prepare a "four factors" analysis for the turbine (Emission Unit CE1) at this station. The analysis should be prepared using the draft EPA guidance noted above.

Preparation of the Round 2 Regional Haze SIP will require extensive planning and review of emission sources in North Dakota. The Department will be working with the Western Regional Air Partnership (WRAP) to prepare the Round 2 SIP. WRAP will be conducting air quality modeling of potential regional emissions reductions in early 2019. The Department asks that your "four factors" analysis be submitted by January 31, 2019.

If you have any questions, please contact David Stroh of my staff at (701)328-5188.

Sincerely,

A handwritten signature in cursive script, reading "Terry O'Clair".

Re: Regional Haze Second Planning Period and Request for "Four Factor" Analysis for the Northern Border Pipeline Company Compressor Station No. 4

Dear Mr. O'Clair:

This letter has been prepared in response to a request by the North Dakota Department of Environmental Quality (NDDEQ) to complete a "four factors" analysis¹ by January 31, 2019 for Northern Border Pipeline Company's (NBPL) Compressor Station No. 4 (CS4). The main intent of this letter is to provide the four factor analysis requested for the facility turbine. However, our review of related material raised several questions, and the attached four factor analysis includes supplementary information. The attachment includes:

- The four-factor analysis considering NOx control of the facility turbine;
- A request for feedback from NDDEQ to clarify the screening or selection criteria that concludes a four-factor analysis is warranted;
- Questions regarding Western Regional Air Partnership emission inventory parameters, such as exhaust temperature, that are relevant for dispersion modeling; and
- Compressor Station #4 location and turbine stack parameters.

As discussed in the attachment, NBPL believes the NOx control cost effectiveness for two available add-on control technologies exceed a reasonable cost threshold. Please contact me if there are any questions or comments at 402-492-7465. Thank you for your review and consideration of this submittal.

Sincerely,

Ruth Jensen
Air Quality Specialist

Attachments: Attachment 1: Compressor Station No. 4 – Four Factor Analysis and Related Questions and Comments

cc. David Stroh, NDDEQ

¹ Section 16 A(g)(1) of the Clean Air Act
13710 FNB Parkway, Suite 300

Attachment 1:

Compressor Station No. 4 – Four Factor Analysis and Related Questions and Comments

This attachment includes the four factor analysis for Compressor Station No. 4, as well as a request for feedback on the NDDEQ screening and selection process that concluded the analysis is warranted, and comments regarding potential air quality modeling and source characteristics.

Four-Factor Analysis for Compressor Station No. 4

Northern Border Pipeline Company's Compressor Station No. 4 is located in McKenzie County, North Dakota and operates under NDDEQ permit number T5-O84001. NDDEQ has requested a four factors analysis associated with its regional haze second planning period (Round 2) State Implementation Plan (SIP). As discussed below, Northern Border would appreciate additional insight into the screening and selection criteria that determined this analysis is needed. The four factor analysis considers application of NO_x control on the facility combustion turbine, and the analysis follows EPA's draft guidance document² and standard methodologies from the EPA Control Cost Manual that are recommended in section 7 of the EPA guidance document.

CS4 includes a 20,000 horsepower (hp) simple cycle natural gas-fired combustion turbine that drives a natural gas compressor. The facility also includes a small emergency generator. Control cost effectiveness is not reviewed for the emergency generator in the four factor analysis because of its very limited run time. The turbine is a Rolls Royce Avon unit with a diffusion flame combustor.

The manufacturer does not offer a burner retrofit option for "lean premixed" combustion, which would decrease NO_x emissions, so other control options are considered. Despite the lack of retrofit burner technology, turbines with standard burners are still relatively low emitting combustion sources (i.e., emissions are relatively low in comparison to other combustion devices such as boilers or engines and other fuel types).

Factor #1 – NO_x Emissions Controls and Control Cost

The pollutant of concern for a natural gas-fired turbine is nitrogen oxides (NO_x). As noted above, the Avon turbine does not offer a low NO_x combustor (lean premixed combustion) as a retrofit option. The EPA guidance document indicates that both retrofit and replacement should be considered. However, replacement costs for a 20,000 hp unit would be exorbitant and more than an order of magnitude higher than the two add-on control options discussed below. The achieved emissions level for replacement would be similar to the controlled NO_x emissions discussed below, thus NO_x cost effectiveness would be more than an order of magnitude higher and exceed \$100,000 per ton. Replacement is not discussed further in this analysis.

Since combustion control is also not an option, the remaining add-on control technologies applicable to a combustion turbine are selective catalytic reduction (SCR) or water/steam injection. Consistent with the EPA guidance document, methodologies from the EPA Control Cost Manual are used to evaluate the NO_x control cost effectiveness for these two technologies.

² Draft Guidance on Progress Tracking Metrics, Long-term Strategies, Reasonable Progress Goals and Other Requirements for Regional Haze State Implementation Plans for the Second Implementation Period, EPA document number EPA-457/P-16-001 (July 2016).

SCR control cost analysis

SCR has had limited application as a retrofit control option for natural gas-fired compressor drivers. In addition to Control Cost Manual methods, costs for the analysis are based on several sources, including:

- A Department of Energy (DOE) Report, “Cost Analysis of NO_x Control Alternatives for Stationary Gas Turbines.”³
- Analysis conducted by the Pennsylvania Department of Environmental Protection (PADEP)⁴ associated with NO_x control requirements for a general permit program, which included SCR and associated reagent costs (as “Total Capital Investment”) for turbines.
- Actual design and installation costs from a recent pipeline installation that were presented to PADEP during recent revisions to the general permit program.
- Capital cost comparison to EPA’s Control Strategy Tool (CoST) software, which is cited in the EPA guidance document.

Table 1 presents the cost details and the source for specific itemized cost elements. Primary assumptions for the analysis include:

- A capital cost of \$720,000 to achieve 80% reduction in NO_x. This control efficiency would achieve 37 tons per year (TPY) of NO_x reductions with 74% annual utilization (i.e., 6500 operating hours).
 - This cost is conservative, and may be very low based on available references. Costs from the PA DEP analysis are higher and the CoST software estimate would be more than double.
- Uncontrolled emissions are based on the 1997 performance test, and these actual emissions (approximately 100 ppmv) from testing at full load are nominally higher than the results from numerous portable analyzer tests conducted in the last fifteen years. The turbine frequently runs at marginally lower load and NO_x emissions decrease at lower load.
- Utilization was reviewed for five years, and the analysis presented in the tables below is based on 6,500 annual operating hours (74% utilization) which is marginally higher than the 5-year average of approximately 6,000 annual operating hours.
- Installation costs based on the real-world example for SCR installed on a smaller unit were *not* scaled based on the unit size. *Direct installation* costs from the real world example are higher than the generic assumptions in the EPA Control Cost Manual, but these are conservative assumptions because some costs (e.g., site preparation, foundation and supports) would likely be higher for the larger unit at CS4. Some *indirect installation* costs are lower than the generic assumptions in the EPA Control Cost Manual, but the “real world” costs are used in this analysis. The default Cost Manual assumptions (i.e., “multipliers” that were not used in the analysis) are shown in Table 1 with ~~striketrough~~ text.
- Reagent costs are from the PA DEP analysis and usage / cost is scaled based on the relative mass emissions of NO_x.

³ “Cost Analysis of NO_x Control Alternatives for Stationary Gas Turbines,” Department of Energy, Prepared by ONSITE SYCOM Energy Corporation under Contract No. DE-FC02-97CHIO877 (November 1999).

⁴ “Technical Support Document, General Permit GP-5” Pennsylvania Department of Environmental Protection (January 2013).

- EPA Control Cost Manual factors and assumptions from similar EPA analysis are used for other cost elements.

Using a conservative approach to determine cost-effectiveness the resulting NO_x control cost is estimated to be \$14,435 per ton. Even using this approach, this is above a reasonable cost threshold. If NDDEQ disagrees, NBPL requests an opportunity to further confirm and/or adjust the conservatively low estimates included for several assumptions, especially for the equipment capital cost.

Water injection control cost analysis

Water injection control is a technology that was applied to turbines over two decades ago, but has had very limited use in recent years, as combustion controls or SCR have been employed. A key concern with water injection is significant increases in emissions of products of incomplete combustion such as carbon monoxide (CO). The manufacturer estimates a five to eight fold increase in CO, which may necessitate installation of an oxidation catalyst, with a cost similar to the NO_x technology. Thus, environmental and economic implications are broader than reflected in the NO_x control cost effectiveness.

The basis for water injection costs and other assumptions include:

- A capital cost of \$2.25 million to achieve 25 ppmv NO_x (i.e., approximately 75% reduction from uncontrolled emissions). This control efficiency would achieve 35 tons per year of NO_x reductions with 65% annual utilization.
- Assumptions for utilization and uncontrolled emissions as discussed above for SCR.
- The technology life of fifteen years is based on the DOE Report.
- EPA Control Cost Manual factors and assumptions from similar EPA analysis are used for most other cost elements.
- Costs are not considered for add-on control to mitigate increases in CO and other emissions.

Table 2 presents the cost details and the resulting NO_x cost effectiveness is \$20,160 per ton. This would appear to be above a reasonable cost threshold.

Factor #2 – Time Necessary for Compliance

Both NO_x control technologies would require a timeline of 18 months to two years. This time is required for engineering design, permitting, site preparation, installation, commissioning, and startup. A longer schedule could be required because previous retrofit installations of SCR on natural gas transmission compressor drivers are very limited, and have resulted in extended commissioning periods to address performance issues with the reagent control system (e.g., ability of the reagent flow control to adequately respond to emissions changes as pipeline demand changes turbine load and NO_x emissions). The schedule would also need to consider the timing of facility outage to ensure that natural gas demand is not affected by the lost compression capacity.

Factor #3 – Energy and Non-Air Environmental Impacts

As briefly noted above, both NO_x control technologies result in a fuel penalty and require use of electricity to drive pumps, etc. The penalty is more severe for water injection, and the DOE report estimates a 3.5% performance loss. Performance loss and electrical usage would increase greenhouse gas (GHG) emissions from the facility. Both technologies introduce other air impacts – e.g., ammonia emissions (which are a particulate precursor) from SCR and relatively large increases in CO and other “products of incomplete” (“PICs”, such as aldehyde emissions) from water injection.

The turbine manufacturer estimates a 5 to 8 fold increase in CO emissions, which may result in the need for an oxidation catalyst retrofit installation that incurs costs similar in magnitude to the NO_x control technology cost, with ultimate emissions of post-control PICs similar to the previous uncontrolled level (i.e., 80% reduction after a five-fold increase). Water injection would consume that resource from the local water supply. SCR technology requires use of ammonia or urea as a reagent, and catalysts must be periodically cleaned and replaced (typically 10 year life is anticipated).

Factor #4 – Remaining Useful Life of the Source

As noted in the EPA guidance document, control technology life will likely be shorter than the expected life of the stationary source. That is the case for a combustion turbine. The cost analysis assumes control technology life of ten years for SCR and fifteen years for water injection. These lifetimes are typical for emission control analysis presented in the DOE report and control technology analysis in EPA regulations and regulations from other states. The turbine life is much longer and not limited if standard maintenance requirements are followed.

Summary

In summary, the four factor analysis indicates a NO_x cost effectiveness of \$14,435 per ton or higher. If less conservative assumptions are used (e.g., for SCR cost) the cost per ton would increase. There are deleterious impacts on energy (e.g., efficiency loss), the environment (e.g., ammonia, CO emissions), and other factors (e.g., water use, catalyst disposal, reagent use and transport). NBPL recommends no further control requirements for Compressor Station No. 4.

Source Selection Criteria for Inclusion in Four-Factor Analysis

Section 6.3 of the EPA draft regional haze guidance⁵ addresses how a state may select sources for four-factor analysis based on visibility impacts. While Northern Border Pipeline Company acknowledges that the 2016 guidance requires states to address 80% of the visibility impairment caused by in-state sources, the screening analysis and/or selection criteria have not been provided.

It is unclear how the Northern Border Pipeline Company Compressor Station No. 4 (CS4) has been selected for inclusion in the second planning period (Round 2) NDDEQ regional haze reasonable progress analysis. We would appreciate additional insight into that decision. The February 24, 2010 North Dakota regional haze SIP noted a lower emitting turbine replacement in 2005 resulting in elimination of CS4 from further consideration based on actual emissions from the source and the distance of CS4 to the Theodore Roosevelt National Park (TRNP) (nearest Class I Federal area).

“The Northern Border Pipeline Company Compressor Station No. 4 is powered by a natural gas turbine. In 2005, Northern Border replaced this turbine with a lower emitting turbine. From 2006-2008, the average nitrogen oxides plus sulfur dioxide emissions were 118 tons per year for a Q/D of 6.6. Because of the installation of the lower emitting turbine, this facility was eliminated from consideration of additional controls during this planning period.”⁶

Please note that this quote includes an error, because the lower emitting unit was installed in the early 1990s and not 2005. However, the lower emission levels noted were appropriately used in the 2006-2008 analysis and supported the conclusion that added controls were not needed. We would appreciate insight into recent screening or other analysis conducted that concludes additional analysis is warranted for CS4.

Western Regional Air Partnership (WRAP) Inventory for Modeling

A review of the CS4 2014 base case emission inventory spreadsheet⁷ appears to contain incorrect stack parameters for facility equipment (e.g., stack temperature of 500). Assuming that the engineering units are Fahrenheit, the significant difference from actual, higher exhaust temperature would result in increased buoyancy plume rise and dispersion from the turbine. The column headings in the WRAP inventory spreadsheet should state the units for each stack parameter. The parameters should be reviewed and cross checked with individual permits or source test data to ensure proper model inputs. For example, information recently provided to NDDEQ indicated an exhaust temperature of 805 °F, and we assume this parameter will be updated in the modeling file.

⁵ EPA Office of Air Quality Planning and Standards Air Quality Policy Division, Draft Guidance on Progress Tracking Metrics, Long-term Strategies, Reasonable Progress Goals and Other Requirements for Regional Haze State Implementation Plans for the Second Implementation Period, EPA-457/P-16-001, July 2016

⁶ North Dakota State Implementation Plan for Regional Haze, February 24, 2010; page 199

⁷ https://deq.nd.gov/publications/aq/planning/regionalHaze/RegHazDocuments/Main_SIP_Sections_1-12.pdf

⁷ https://www.wrapair2.org/pdf/WESTAR_OGWG_Emissions_Inventory_2014_Webdistribution_081018.xlsx

Further, care must be taken when including emergency generators to accurately reflect the low utilization rate for this source group. Conservatively dividing the annual actual emissions by 8,760 to develop a commensurate hourly emission rate does not accurately reflect impacts from this source group. Including these as continuous lower emitting sources for 8,760 hours does not accurately pair the emission events with the meteorological condition during the few hours of operation over the year.

In summary, it is unclear how NDDEQ established a visibility impact level and/or screened the source inventory to serve as a threshold below which no further analysis of additional control measures will be undertaken – and therefore exclude a “four factors” analysis.

Re: Regional Haze Second Planning Period and Request for "Four Factor" Analysis for the Northern
Border Pipeline Company Compressor Station No. 4 – Revision 1

Dear Mr. O'Clair:

This letter has been prepared in response to a request by the North Dakota Department of Health (NDDH) to complete a "four factors" analysis¹ for Northern Border Pipeline Company's (NBPL) Compressor Station No. 4 (CS4). The main intent of this letter is to provide the four factor analysis requested for the facility turbine and update a December letter from NBPL. This letter responds to NDDH comments and discussion in a recent conference call. The attachment includes the four-factor analysis considering NOx control of the facility turbine, and addresses NDDH comments:

As discussed in the attachment, NBPL believes the NOx control cost effectiveness for SCR exceeds a reasonable cost threshold and water injection is not technologically feasible. Please contact me if there are any questions or comments at 402-492-7465. Thank you for your review and consideration of this submittal.

Sincerely,

Ruth Jensen
Air Quality Specialist

Attachments: Attachment 1: Compressor Station No. 4 – Four Factor Analysis (Revision 1)

Attachment 1:

Compressor Station No. 4 – Four Factor Analysis (February 2019 Revision)

This attachment includes the updated four factor analysis for Compressor Station No. 4.

Four-Factor Analysis for Compressor Station No. 4

Northern Border Pipeline Company's Compressor Station No. 4 is located in McKenzie County, North Dakota and operates under NDDH permit number T5-O84001. NDDH has requested a four factors analysis associated with its regional haze second planning period (Round 2) State Implementation Plan (SIP). Northern Border provided a letter submittal in December 2018. NDDH responded in January and NDDH comments were discussed in a conference call. This document updates the four factor analysis based on the comments and discussion. The four factor analysis considers application of NO_x control on the facility combustion turbine, and the analysis follows EPA's draft guidance document¹ and standard methodologies from the EPA Control Cost Manual that are recommended in section 7 of the EPA guidance document.

CS4 includes a 20,000 horsepower (hp) simple cycle natural gas-fired combustion turbine that drives a natural gas compressor. The facility also includes a small emergency generator. Control cost effectiveness is not reviewed for the emergency generator in the four factor analysis because of its very limited run time. The turbine is a Rolls Royce Avon unit with a diffusion flame combustor.

The manufacturer does not offer a burner retrofit option for "lean premixed" combustion, which would decrease NO_x emissions, so other control options are considered. Despite the lack of retrofit burner technology, turbines with standard burners are still relatively low emitting combustion sources (i.e., emissions are relatively low in comparison to other combustion devices such as boilers or engines and other fuel types).

Factor #1 – NO_x Emissions Controls and Control Cost

The pollutant of concern for a natural gas-fired turbine is nitrogen oxides (NO_x). As noted above, the Avon turbine does not offer a low NO_x combustor (lean premixed combustion) as a retrofit option. The EPA guidance document indicates that both retrofit and replacement should be considered. However, replacement costs for a 20,000 hp unit would be exorbitant and more than an order of magnitude higher than the two add-on control options discussed below. The achieved emissions level for replacement would be similar to the controlled NO_x emissions discussed below, thus NO_x cost effectiveness would be more than an order of magnitude higher and exceed \$100,000 per ton. Replacement is not discussed further in this analysis.

Since combustion control is also not an option, the remaining add-on control technologies applicable to a combustion turbine are selective catalytic reduction (SCR) or water/steam injection. As discussed below, the latter is not technologically feasible for a turbine driving a natural gas compressor. Consistent with the EPA guidance document, methodologies from the EPA Control Cost Manual are used to evaluate the NO_x control cost effectiveness for SCR.

¹ Draft Guidance on Progress Tracking Metrics, Long-term Strategies, Reasonable Progress Goals and Other Requirements for Regional Haze State Implementation Plans for the Second Implementation Period, EPA document number EPA-457/P-16-001 (July 2016).

Analysis was not conducted for water injection due to its very limited application to industrial turbines. Additional discussion on water injection technical feasibility is provided below and cost effectiveness could be evaluated if desired.

SCR control cost analysis

SCR has had limited application as a retrofit control option for natural gas-fired compressor drivers. The initial analysis presented in the December letter included several sources, such as a Department of Energy report and information on design, engineering, and installation from a compressor station application in the northeast U.S. Based on NDDH comments and the conference call discussion, the analysis was revisited to primarily rely on Control Cost Manual methods. A key input for the analysis is the capital cost, and a 2016 Control Cost Manual supplementary document that updated the SCR chapter² was used to estimate the capital cost.

Table 1 presents the cost details and the source for specific itemized cost elements. In addition to the SCR capital cost, an important assumption for the analysis is the estimate of *actual* NO_x emissions. The current and anticipated ongoing operation of the turbine at CS4 is lower than full load. Thus, actual emissions should be based on the best estimate of ongoing operation and associated NO_x emissions. Primary assumptions for the analysis include:

- A capital cost of \$3,740,000 to achieve 80% reduction in NO_x; based on Chapter 2 of the Control Cost Manual with the cost adjusted to 2018 using the consumer price index (CPI).
- Uncontrolled emissions are based on a best estimate of actual emissions. The average value from 26 portable analyzer tests conducted from 2004 through 2017 is 0.264 lb/MMBtu, and the average operating load for these tests was about 70% load. This is consistent with average annual load in recent years and anticipated future operation.
 - The annual fuel rate and natural gas heating value, averaged for five year (from 2014 through 2018) is used in conjunction with the emission rate to calculate the average hourly emission rate of 38.2 lb/hr shown in Table 1.
- Capital cost recovery is based on a twenty year life and interest rate of 5.25% (consistent with the current prime rate). Longer life is not appropriate for catalytic systems which typically have a warranty of no longer than five years.
- Utilization was reviewed for five years, and the analysis is based on 6,500 annual operating hours (74% utilization) which is marginally higher than the 5-year average of approximately 5,740 annual operating hours. The marginally higher utilization assumed is expected to be a conservative estimate of ongoing annual operation.
 - The resulting uncontrolled annual NO_x emissions are approximately 124 tons and the annual reduction at 80% control is 99 tons.
- Most other costs (direct and indirect installation costs, etc.) are based on the Control Cost Manual.
- Reagent costs are from a current cost quote for an SCR installation with usage / cost scaled based on the relative mass emissions of NO_x.

² "Chapter 2, Selective Catalytic Reduction," EPA update to Control Cost Manual, Table 2.1b (May 2016).

The resulting NO_x control cost is estimated to be \$13,280 per ton. NBPL believes this is well above a reasonable cost threshold. If NDDH disagrees, NBPL requests an opportunity to further review several assumptions to further refine the analysis.

Water injection control analysis

Water injection control is a technology that was applied to turbines over two decades ago, but has had very limited use in recent years, as combustion controls or SCR have been employed. A key concern with water injection is significant increases in emissions of products of incomplete combustion such as carbon monoxide (CO). NO_x reductions would be lower than for the SCR analysis discussed above. For example, vendors may estimate a NO_x reduction of 75% at full load, but at the reduced operation that will occur at CS4, lower uncontrolled NO_x emissions and less reduction would be anticipated. Manufacturers estimate a five to eight fold increase in CO. This may necessitate installation of an oxidation catalyst, with a cost similar to the NO_x technology costs. In addition, a larger increase in CO emissions will occur at the reduced load operation typical for the CS4 turbine.

Performance could also be worse due to operational challenges, because this technology has not been demonstrated for natural gas transmission facilities, at least not in recent years. This technology was supplanted by low emissions combustion, which is not available for the Avon turbine at CS4. For water injection, NBPL believes that environmental and technological issues result in a conclusion that water/steam injection is not technologically feasible. A cost effectiveness analysis is not presented, but could be completed if desired. Costs would be incurred beyond base costs for NO_x control, including: (1) addressing emissions of CO and other products of incomplete combustion, and (2) contingencies associated with implementing a technology with very limited historical application and no installations at compressor stations in recent years.

Factor #2 – Time Necessary for Compliance

Both NO_x control technologies would require a timeline of three years or more. This time is required for engineering design, permitting, site preparation, installation, commissioning, and startup. A schedule up to five years could be required because previous retrofit installations of SCR on natural gas transmission compressor drivers are very limited, and have resulted in extended commissioning periods to address performance issues with the reagent control system (e.g., ability of the reagent flow control to adequately respond to emissions changes as pipeline demand changes turbine load and NO_x emissions). The schedule would also need to consider the timing of facility outage to ensure that natural gas demand is not affected by the lost compression capacity.

Factor #3 – Energy and Non-Air Environmental Impacts

As briefly noted above, both NO_x control technologies result in a fuel penalty and require use of electricity to drive pumps, etc. The penalty is more severe for water injection, and the DOE report estimates a 3.5% performance loss. Performance loss and electrical usage would increase greenhouse gas (GHG) emissions from the facility. Both technologies introduce other air impacts – e.g., ammonia emissions (which are a particulate precursor) from SCR and relatively

large increases in CO and other “products of incomplete combustion” (“PICs”, such as aldehyde emissions) from water injection.

The turbine manufacturer estimates a 5 to 8 fold increase in CO emissions, which may result in the need for an oxidation catalyst retrofit installation that incurs costs similar in magnitude to the NOx control technology cost, with ultimate emissions of post-control PICs similar to the previous uncontrolled level (i.e., 80% reduction after a five-fold increase). The emission levels would be further increased (with implications for catalyst design and cost) due to reduced load operation for the turbine. Water injection would consume that resource from the local water supply. SCR technology requires use of ammonia or urea as a reagent, and catalysts must be periodically cleaned and replaced.

Factor #4 – Remaining Useful Life of the Source

As noted in the EPA guidance document, control technology life will likely be shorter than the expected life of the stationary source. That is the case for a combustion turbine. The cost analysis assumes control technology life of twenty years for SCR. A twenty year lifetime exceeds typical estimates for emission control analysis presented in the DOE report and control technology analysis in EPA regulations and regulations from other states, and greatly exceeds the technology warranty. The turbine life is much longer and not limited if standard maintenance requirements are followed.

Summary

In summary, the four factor analysis indicates a NOx cost effectiveness of over \$13,000 per ton for SCR. Water/steam injection is not technologically feasible. There are deleterious impacts on energy (e.g., efficiency loss), the environment (e.g., ammonia, CO emissions), and other factors (e.g., water use, catalyst disposal, reagent use and transport). NBPL recommends no further control requirements for Compressor Station No. 4.

Re: Regional Haze 4-Factors Analysis
Compressor Station No. 4

Dear Ms. Jensen:

The North Dakota Department of Health (Department) has conducted an initial review of your four-factors analysis for Northern Border Pipeline Company (NBPL) – Compressor Station No. 4 (CS4) in North Dakota. With respect to the analysis we have the following comments:

1. The expected life of the selective catalytic reduction (SCR) system listed in the economic analysis is 10 years. We believe a more appropriate life of an SCR for a natural gas-fired unit is 20-30 years (see EPA's Control Cost Manual, Section 4.2, Chapter 2, p 2-78). The economic analysis must be redone using an appropriate expected life of the SCR and water injection control system.
2. The 7% interest rate used in the economic analysis appears to be too high. EPA's Control Cost Manual states "When performing cost analysis, it is important to ensure that the correct interest rate is being used. Because this Manual is concerned with estimating private costs, **the correct interest rate to use is the nominal interest rate, which is the rate firms actually face** [emphasis added]". The manual further states "For input to analysis of rulemakings, assessments of private cost should be prepared using firm-specific nominal interest rates if possible, or the bank prime rate if firm-specific interest rates cannot be estimated or verified." The current bank prime rate is 5.25%. We believe an interest rate no higher than 5.25% should be used. Attached to this letter is an email we received from EPA regarding this matter. The economic analysis must be redone using an appropriate interest rate.
3. The baseline emission rate for the unit appears to be too low. The baseline emission rate should represent a realistic depiction of anticipated future annual emissions for the source. In general, estimates of anticipated emissions are based upon actual emissions from the baseline period (two-year period) that are representative of expected future emissions. Although no baseline emission rate is stated in the analysis, a back-calculation indicates a

baseline emission rate of 46.5 tons of NO_x per year (i.e. 37.22 tons reduction divided by 80% reduction for SCR). The 2016 and 2017 Annual Emission Inventory Reports submitted by Northern Border Pipeline Co. indicated an average of 171 tons of NO_x per year based on 1997 emissions testing results. Based on more recent testing at this unit, we believe the emission rate is even higher. The economic analysis must be redone using an appropriate baseline emission rate. Proper documentation should be provided explaining why the baseline selected for the facility is required in cases where the baseline emissions are not easily understood. As an example of our concern for the baseline emission rate of 46.5 tons of NO_x per year and our expected thoroughness of calculations, please see the attached calculation summary.

4. Documentation must be provided for the cost estimates. Any references, other than the Control Cost Manual, must either be submitted with the analysis or a website address provided where the documents can be downloaded. Documentation must also be provided for any scaling that was done to obtain the cost estimates.

The Department's response to questions posed by NBPL in the four-factor analysis are:

5. NBPL CS4 was selected as a source to perform a four-factor analysis based on the 2012-2016 average combined NO_x and SO₂ emissions of 157 tons per year, with a distance to the North Unit of Theodore Roosevelt National Park of 18 km. This results in a Q/d (tons/km) of 9, which is in line with the other sources selected for analysis and the 2016 draft guidance. Q/d was a metric used during Regional Haze Round 1 to identify sources for evaluation. Similarly, Q/d is also being used for initial source selection for analysis in Regional Haze Round 2.

Using the average emissions from 2012-2016 was beneficial (looking at Q/d) for NBPL CS4, since operating hours in 2014 and 2015 indicate 44% utilization, compared to a utilization average of 88% in 2012, 2013, 2016 and 2017. If only the last two years of NO_x emissions data (2016 and 2017) provided to the Department are utilized, the Q/d becomes 11.3 (*note: NO_x appears to have been underreported by NBPL CS4 based on test results submitted to the Department; see Number 3*). Using corrected data that has not been underreported, Q/d would become 14.1 (again only using NO_x); therefore, NBPL CS4 was identified as a source to conduct a four-factor analysis.

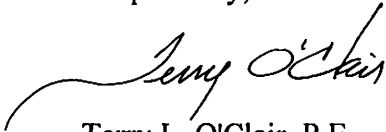

Through the four-factor analysis, North Dakota is addressing approximately 80% of the visibility impairment (nitrates and sulfates) as determined by the IMPROVE monitoring network in North Dakota (<http://vista.cira.colostate.edu/Improve/aqrv-summaries/>). Sending four factor letters to the ten highest Q/d facilities in North Dakota addresses 94% of the 2012-2016 emissions from stationary sources included in the 2014 National Emissions Inventory (NEI), which is being used for the 2014 baseline modeling performed by the Western Regional Air Partnership (WRAP). Q/d for the sources selected in North Dakota ranged from 7 to 164.

See attachment containing detailed emissions information and distance to Class 1 areas used to select the sources for a four-factor analysis.

6. The Department will ensure that the information used in the 2014 Baseline Modeling, completed by WRAP, will be consistent with the information provided by Northern Border Pipeline Co. for Compressor Station No. 4. Thank you for providing the correct stack parameters for the facility equipment.

The revised analysis should be submitted as soon as possible. If you have any questions, please contact David Stroh or Tom Bachman of my staff at (701) 328-5188.

Respectfully,

CAUTION: This email originated from an outside source. Do not click links or open attachments unless you know they are safe.

Hi Tom-

The interest rate recommended by EPA can vary by firm or industry, but the bank prime rate is a default rate that can be used for annualization of capital costs. The most recent bank prime rate (currently ~5.25%) can be found on the Federal Reserve website here:

<https://www.federalreserve.gov/releases/h15/>

Also, consult the somewhat recently revised Cost Estimation chapter of EPA's Control Cost Manual. See discussion of the bank prime rate in Section 2.5.2, Interest Rates:

https://www.epa.gov/sites/production/files/2017-12/documents/epacmcostestimationmethodchapter_7thedition_2017.pdf

I hope that is helpful.

Happy Holidays!

Aaron

Subject: Regional Haze Economic Analyses

Aaron/Jaslyn:

Now that our sources are working on four-factor analyses (and GRE is contemplating a revised BART analysis for Coal Creek Station), a question regarding the analysis has come up. That is – what is the appropriate interest rate to be used in the economic analysis to determine annualized costs? In the past we have generally used 7%; however some analyses used a lower value. Given current low interest rates, is 7% still valid?

Any information you can provide will be appreciated!

The attached file is data you provided. Average for all is 0.264 lb/MMBtu which is the NOx emission rate used in the cost analysis XLS included in the submittal.

Let me know if you have additional questions.

Thanks.

Beulah, ND 58523

Re: Regional Haze
Second Planning Period

Dear Mr. Whitley:

The Department of Health (Department) has begun work on the second planning period (Round 2) State Implementation Plan (SIP) for regional haze. In Round 1 of the regional planning process, the emphasis was on Best Available Retrofit Technology (BART) and making reasonable progress towards the national visibility goal. In Round 2, there are no BART requirements; therefore, we will focus on making reasonable progress. The reasonable progress analysis will be made using the four factors in Section 169A(g)(1) of the Clean Air Act:

The four factors are:

1. The cost of compliance
2. The time necessary to achieve compliance
3. The energy and non-air quality environmental impact of compliance; and
4. The remaining useful life of any existing source subject to such requirements

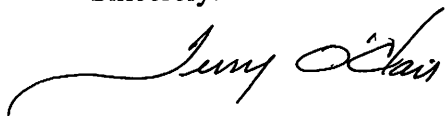

Guidance provided by the U.S. Environmental Protection Agency (Draft Guidance on Progress Tracking Metrics, Long Term Strategies, Reasonable Progress Goals and Other Requirements for Regional Haze State Implementation Plans for the Second Implementation Period at https://www.epa.gov/sites/production/files/2016-07/documents/draft_regional_haze_guidance_july_2016.pdf) indicates the Department must address 80% of the visibility impairment caused by in-state sources. Data from the IMPROVE monitoring sites at Theodore Roosevelt National Park (TRNP) and Lostwood Wilderness Area (LWA) indicate that sulfates and nitrates continue to be the largest contributors to visibility impairment in these areas. The primary precursors of sulfates and nitrates are emissions of sulfur dioxide (SO₂) and nitrogen oxides (NO_x).

The Great Plains Synfuels Plant has been identified as a significant source of SO₂ and NO_x emissions. Therefore, the Department requests that you prepare a “four factors” analysis for your facility. The analysis should be prepared using the draft EPA guidance noted above. The analysis should include all source units that emit through the main stack as well as the flares at the facility.

Preparation of the Round 2 Regional Haze SIP will require extensive planning and review of emission sources in North Dakota. The Department will be working with the Western Regional Air Partnership (WRAP) to prepare the Round 2 SIP. WRAP will be conducting air quality modeling of potential regional emissions reductions in early 2019. The Department asks that your "four factors" analysis be submitted by January 31, 2019.

If you have any questions, please contact David Stroh of my staff at (701)328-5188.

Sincerely,

A handwritten signature in cursive script, appearing to read "Terry O'Clair", written in black ink.

RE: Great Plains Synfuels Plant Regional Haze Second Planning Period Reasonable Progress
Four Factor Analysis

Dear Mr. O'Clair:

At the request of the North Dakota Department of Health (NDDH), Dakota Gasification Company (DGC) has prepared a four factor analysis for the NDDH's Regional Haze Second Planning Period Reasonable Progress analysis. As part of this analysis NO_x and SO₂ emissions were evaluated at the Great Plains Synfuels Plant (GPSP). The four factor analysis is attached to this letter.

In addition to the four factor analysis, the NDDH requested DGC to provide hourly NO_x and SO₂ emissions rates to be included as part of the Western Regional Air Partnership (WRAP) visibility modeling. The rates provided for the GPSP facility represent actual maximum rolling 24-hour average emission rates in lb/hr and should not be construed to represent actual long-term average baseline emissions rates or proposed permit emission limits. The following three sources were identified by the NDDH to be included in the modeling effort.

Emission Source	NO _x Emission Rate lb/hr	SO ₂ Emission Rate lb/hr
Main Stack ^(Note 1)	944	1,681
Main Flare	224	1,598
Startup Flare	171	334

Note 1. Main Stack emission rates include emissions from three (3) Riley Boilers and two (2) Superheaters.

Based on the results of the four factor analysis, there are no additional reductions expected from current baseline emission rates either due to the technical infeasibility of installing additional emissions controls, or the control options having excessive costs and, therefore, not being cost effective.

DGC looks forward to working with the NDDH in establishing the state's reasonable progress goals. Should you or your staff have any questions regarding the GPSP four factor analysis or

inputs to the WRAP modeling, please do not hesitate to contact me at (701) 873-6619 or by email at dwhitley@bepc.com.

Sincerely,

EXECUTIVE SUMMARY

The Great Plain Synfuels Plant (GPSP), located near Mercer County, ND, commenced operation in 1984. The facility is owned and operated by Basin Electric Power Cooperative (Basin Electric) through its for-profit subsidiary, Dakota Gasification Company (DGC), which acquired the facility in 1988. The facility uses lignite coal to produce synthetic natural gas (SNG), fertilizers, and other products utilizing coal gasification process and is the only facility of its kind in the U.S. Lignite is delivered from the nearby Freedom mine.

On July 1, 1999, the U.S. Environmental Protection Agency (EPA) published regulations implementing Section 169A of the Clean Air Act (CAA), establishing a comprehensive visibility protection program for Federal Class I areas (the Regional Haze Rule).¹ The Regional Haze Rule requires each state to develop, and submit for approval by EPA, a state implementation plan (SIP) detailing the state's plan to protect visibility in Class I areas. The Regional Haze Rule established a schedule setting forth deadlines by which the States must submit their initial regional haze SIPs and subsequent revisions to the SIPs. Regional Haze SIPs for the initial planning period were due in 2007, with subsequent SIP updates due in 2018 and every 10 years thereafter.² Second planning period Regional Haze SIPs must be submitted to EPA for review by July 31, 2021.

At the request of the North Dakota Department of Health (NDDH), a Four Factor Analysis was prepared for GPSP. The analysis identified sulfur dioxide (SO₂) and nitrogen oxides (NO_x) control options for the three Riley Boilers, two Superheaters, auxiliary Package Boiler, Main Flare, and Startup Flare, and evaluated each of the control measures for the following four statutory factors:

1. The estimated cost of compliance;
2. The time necessary for compliance;
3. The energy and non-air quality environmental impacts of compliance; and
4. The remaining useful life of any potentially affected anthropogenic source of visibility impairment.

¹ 64 FR 35713

² On January 10, 2017, EPA made a one-time adjustment to the due date for the second implementation period SIPs (2018 – 2028) by extending the deadline from July 31, 2018 to July 31, 2021 (82 FR 3078).

The technical feasibility evaluation concluded that there are no technically feasible options for further SO₂ control on the individual sources, including the Riley Boilers, Superheaters, Package Boiler, Main Flare, and Startup Flare. Furthermore, the evaluation concluded that there are no technically feasible options for further NO_x control on the Package Boiler, Main Flare, and Startup Flare. NO_x control strategy options that are evaluated as part of the Four Factor Analysis for the Riley Boilers and Superheaters are included in Table ES-1 and Table ES-2. The tables also show baseline emission rates and estimated emission reductions for each control option.

Table ES-1. NO_x Control Options for GPSP Riley Boilers

Control Technology	NO _x Emission Rate (Note 1) lb/hr	% Reduction from Baseline Emission Rate
Selective Catalytic Reduction (tail-end) (Note 2)	103	80%
Baseline (Combustion Optimization / OFA / LNB)	517	--

Note 1. Emission rates shown represent average emission rates that the control options would be expected to achieve on an ongoing long-term basis under normal operating conditions for GPSP Riley Boilers. Emission rates are provided for comparative purposes, and should not be construed to represent proposed emission limits. Corresponding permit limits must be evaluated on an emission source type and control system-specific basis.

Note 2. TE-SCR has not been installed on a North Dakota lignite-fired unit or lignite-derived-fuel unit, and extended trials would be needed to better understand the design and operation of TE-SCR on the GPSP Riley Boilers. Nevertheless, during the initial planning period, NDDH evaluated the costs and cost-effectiveness of the control system on the Riley Boilers. TE-SCR will therefore be carried forward to the Four Factor Analysis to present hypothetical costs since the Department included it in the reasonable progress analysis for GPSP during the first planning period; however, technical feasibility has never actually been demonstrated for TE-SCR for lignite-based fuels.

Table ES-2. NO_x Control Options for GPSP Superheaters

Control Technology	NO _x Emission Rate (Note 1) lb/hr	% Reduction from Baseline Emission Rate
Combustion Optimization	42	5%
Baseline (Combustion Optimization / FGR / LNB)	44	--

Note 1. Emission rates shown represent average emission rates that the control options would be expected to achieve on an ongoing long-term basis under normal operating conditions for GPSP Superheaters. Emission rates are provided for comparative purposes, and should not be construed to represent proposed emission limits. Corresponding permit limits must be evaluated on a source-specific and control system-specific basis.

Costs of Compliance (Statutory Factor One)

Capital and operating and maintenance (O&M) cost estimates were developed for each of the NO_x control options. The GPSP cost estimates are conceptual in nature; thus, S&L did not procure equipment quotes specifically for the control system upgrades.

Table ES-3 includes estimated costs for NO_x control options for the Riley Boilers combined and the two Superheaters combined. The table provides the estimated annualized capital and O&M costs, estimated emissions reductions, and average annual cost effectiveness.

Table ES-3. NO_x Emissions Control System Cost Effectiveness (\$2018)

Unit ^(Note 1)	NO _x Control Option	Total Annual Cost \$/yr	Expected Emission Reduction tons NO _x /yr	Average Annual Cost Effectiveness ^(Note 2) \$/ton NO _x removed
Riley Boilers	TE-SCR	\$69,854,000	1,808	\$38,639
Superheaters	Combustion Optimization	\$229,000	10	\$23,596

Note 1. Costs are provided for the combination of the three Riley Boilers or two Superheaters.

Note 2. Average cost effectiveness for each control option is the total annual cost divided by the expected emission reduction.

Time Necessary for Compliance (Statutory Factor Two)

Table ES-4 provides estimated timeframes needed to implement each of the evaluated control options. Notably, the estimated timeframes do not account for time needed for North Dakota to develop and implement the regulations; nor the amount of time needed for EPA to take proposed and final action to approve North Dakota's SIP.

Table ES-4. NO_x Emissions Control System Implementation Schedule

NO _x Control Option	Design / Specification / Procurement (months)	Detail Design / Fabrication (months)	Construction / Commissioning / Startup (months)	Total (months after SIP approval)
TE-SCR on Riley Boilers	10	18	24	Up to 60 months
Combustion Optimization on Superheaters	2	4	4	Up to 60 months

Energy and Non-Air Quality Environmental Impacts (Statutory Factor Three)

An evaluation of energy impacts indicates that certain control options (e.g., TE-SCR) will increase electrical power requirements due to increased pressure drop. Use of a combustion optimization system for NO_x control may also result in reduced boiler efficiency, which would increase the amount of fuels fired to maintain steam generation. Collateral environmental impacts with regard to TE-SCR include an increase in solid waste generation due to sorbent injection; increases in other stack emission such as CO, VOC and ammonia slip; as well as additional power consumption. A summary of the environmental and energy impact analysis is provided in Table ES-5.

Table ES-5. Summary of Energy and Non-Air Quality Environmental Impacts

Control Option	Collateral Environmental & Energy Impacts
Baseline	<p>GPSP Riley Boilers are currently equipped with WFGD / WESP control systems for SO₂ control. The Riley Boilers and Superheaters are equipped with a combination of LNB, FGR, and OFA for NO_x control. Existing collateral environmental and energy impacts include:</p> <ul style="list-style-type: none"> ➤ Solid WFGD by-product management or disposal ➤ Increased water consumption ➤ Increased electrical power requirements
NO_x Control Options	
Selective Catalytic Reduction (SCR) - Tail End Configuration (Riley Boilers)	<ul style="list-style-type: none"> ➤ Increased electrical power requirements ➤ Increased ammonia slip emissions and potential for ABS emissions ➤ Potential increase in SO₃ emissions ➤ Additional solid waste disposal ➤ Additional NO_x, CO, and VOC emissions from duct firing
Combustion Optimization (Superheaters)	<ul style="list-style-type: none"> ➤ Potential decrease in boiler efficiency to reduce NO_x emissions ➤ Potential increase in CO emissions

Remaining Useful Life (Statutory Factor Four)

Regarding remaining useful life, the GPSP owners do not have an enforceable or suggested remaining useful life that is less than 20 years. However, implementation of control technologies that eliminate any profitability for the facility may have an effect on the remaining life. Nevertheless, a 20 year remaining useful life is evaluated.

1. INTRODUCTION

Sargent & Lundy, L.L.C. (S&L) was hired by Basin Electric's Dakota Gasification Company (DGC) to prepare a reasonable progress four-factor analysis for the control of nitrogen oxides (NO_x) and sulfur dioxide (SO₂) emissions from the Great Plains Synfuels Plant (GPSP). The evaluation is in response to the North Dakota Department of Health's (NDDH) formal letter dated May 18, 2018, attached in Appendix A. The evaluation includes an assessment of potentially available emission reduction measures for the four statutory factors listed in 40 CFR 51.308(f)(2), and takes into consideration U.S. Environmental Protection Agency's (EPA's) *Draft Guidance on Progress Tracking Metrics, Long Term Strategies, Reasonable Progress Goals and Other Requirements for Regional Haze State Implementation Plans for the Second Implementation Period* (the "Draft EPA Guidance").³ Technically feasible NO_x and SO₂ emission reduction measures are evaluated for the following four statutory factors:

- Factor 1: The cost of compliance
- Factor 2: The time necessary to achieve compliance
- Factor 3: The energy and non-air quality environmental impact of compliance
- Factor 4: The remaining useful life of any existing source subject to such requirements

The reasonable progress four factor analysis for the Great Plains Synfuels Plant (the "Four Factor Analysis") is presented in the following sections:

- Section 2: Facility Description** contains information describing the facility, site location, and existing equipment.
- Section 3: Four-Factor Analysis Requirements** provides a brief description of the Regional Haze Program requirements set forth in 40 CFR 51.308.
- Section 4: Baseline SO₂ and NO_x Emissions** establishes representative baseline SO₂ and NO_x emissions for the period 2013 to present.

³ On September 11, 2018, EPA released a "*Regional Haze Reform Roadmap*" announcing its plan to "release a series of implementation tools and guidance documents that will help focus states' efforts and reduce and streamline the time and resources needed to meet the statutory and regulatory requirements for reducing regional haze in National Parks, wildlife refuges, and wilderness areas." EPA stated that it plans to issue a new guidance document on Regional Haze SIP Development by Spring, 2019. Dakota Gasification Company reserves the right to update and modify this four-factor analysis, as needed, to be consistent with any new guidance issued by the agency.

Sections 5-8: NO_x and SO₂ Control Measures identifies potentially available emission control technologies, and evaluates each control option for technical feasibility and effectiveness for each of the Riley Boilers and Superheaters, the Package Boiler, the Main Flare and the Startup Flare.

Section 9: Costs of Compliance (Statutory Factor One) evaluates the cost and cost-effectiveness of each technically feasible control option.

Section 10: Time Necessary for Compliance (Statutory Factor Two) provides typical timelines required to design, engineer, procure, and install the technically feasible control options.

Section 11: Energy and Non-Air Quality Environmental Impacts (Statutory Factor Three) identifies the energy and non-air quality environmental impacts associated with each technically feasible control option.

Section 12: Remaining Useful Life (Statutory Factor Four) includes a discussion of the planned remaining useful life of GPSP, including an evaluation of how remaining useful life affects the cost-effectiveness of each technically feasible control option.

Section 13: Summary

Appendix A: North Dakota Department of Health Letter

Appendix B: GPSP Baseline Emissions

Appendix C: NO_x Control Cost Effectiveness Estimates

2. FACILITY DESCRIPTION

The GPSP, located near Mercer County, ND, commenced operation in 1984. The facility is owned and operated by Basin Electric Power Cooperative (Basin Electric) through its for-profit subsidiary, DGC, which acquired the facility in 1988. The facility uses lignite coal to produce synthetic natural gas (SNG), fertilizers, and other products utilizing coal gasification process and is the only facility of its kind in the U.S. Lignite is delivered from the nearby Freedom mine.

The plant consists of various emission sources, including, but not limited to, the following main sources: three (3) Riley Boilers, two (2) Coen heat transfer superheaters (a.k.a. “Superheaters”), a Main Flare, a Startup Flare, a Backup Flare, and a Rentech Auxiliary Boiler (a.k.a “Package Boiler”). There are additional emission sources at the GPSP; however, the NDDH has confirmed that the emissions from these other sources are not expected to significantly contribute to visibility impairment. As such, only the main sources identified above will be included in this Four Factor Analysis.

The Riley Boilers and Superheaters generate steam required for the gasification process, and for other uses at the facility. Each Riley Boiler fires up to 763 million British thermal units per hour (MMBtu/hr) of fuels and is designed to burn a combination of gasification products, including liquid and gaseous fuels consisting of waste gas, stink gas, tar oil, naphtha/phenol (N/P) blend, lock gas, medium BTU purge gas, and SNG. The Riley Boilers complete regular combustion tuning and are equipped with low NO_x burners (LNB) and a pseudo-overfire air (OFA) system for NO_x control.⁴ The Riley Boilers are also equipped with a single wet flue gas desulfurization (WFGD) system for SO₂ and particulate matter (PM) control, and a wet electrostatic precipitator (WESP) system for acid gas and PM control.

Each Superheater fires up to 169 MMBtu/hr of fuels and is designed to fire SNG and tar oil in combination or up to 100% of either fuel. The Superheaters complete regular combustion tuning and are equipped with LNB and partial

⁴ The GPSP Riley Boilers were upgraded with windbox partitions that provide staging of combustion air to the upper burner compartment similar to overfire air systems, and subsequently provides NO_x reduction.

flue gas recirculation (FGR) for NO_x control. Hot exhaust flue gas from the Superheaters is combined with the WFGD outlet from the Riley Boilers to reheat the flue gas prior to exiting to atmosphere in a common stack.

Due to the nature of the gasification process and various backend components, the facility is equipped with five process gas flares: the Main Flare, Startup Flare, Ammonia Plant Flare, Ammonia Storage Tank Flare, and Backup Flare. Based on discussion with NDDH, only the Main Flare and Startup Flare are evaluated in this Four Factor Analysis; the other flares operate intermittently and/or are not expected to significantly contribute to visibility impairment. The Main Flare and Startup Flares are typically used in times of startup, shutdown, or malfunction to fire numerous process gases purged along different points of the gasification process. The flares are used as an emission control device to combust midstream components prior to emitting to the atmosphere. The Main Flare is where process relief discharges from safety or pressure control vents. The Main Flare has the ability to inject steam at the flare tip for smokeless operation. The Startup Flare is primarily used during the startup of the gasifiers when the raw gas is not of sufficient composition for additional processing. There are currently no NO_x or SO₂ controls on the flares.

The Package Boiler was installed in 2017. It is designed to fire SNG at a rate of 318 MMBtu/hr and provides process steam primarily to the GPSP urea production facility. The Package Boiler is equipped with ultra-low NO_x burners (ULNB) for NO_x control. DGC fires low-to-no sulfur SNG fuel exclusively in the Package Boiler.

3. FOUR-FACTOR ANALYSIS REQUIREMENTS

3.1 REGIONAL HAZE RULE BACKGROUND

Section 169A of the 1977 Amendments to the Clean Air Act (CAA) sets forth a program for protecting visibility in Federal Class I areas which calls for the “prevention of any future, and the remedying of any existing, impairment of visibility in mandatory Federal Class I areas which impairment results from manmade air pollution.” Federal Class I areas include national parks, memorial parks, and wilderness areas over a certain size. Figure 3-1. shows the locations of the 156 federally mandated Class I areas. Federal Class I areas located within North Dakota include the Theodore Roosevelt National Park and the Lostwood National Wildlife Refuge.

Figure 3-1. Federal Class I Areas

On July 1, 1999, the U.S. EPA published regulations implementing Section 169A of the CAA, establishing a comprehensive visibility protection program for Federal Class I areas (the Regional Haze Rule).⁵ The Regional Haze Rule requires each state to develop, and submit for approval by EPA, a state implementation plan (SIP) detailing the state's plan to protect visibility in Class I areas. Regional Haze SIPs must contain such emission limits, schedules of compliance, and other measures as may be necessary to make reasonable progress toward meeting the national visibility goal of achieving visibility in Class 1 areas which reflects natural conditions by 2064.

To address the combined visibility effects of various pollution sources over a wide geographic region, EPA designated five Regional Planning Organizations (RPOs) to assist with the coordination and cooperation needed to address the visibility issue. The five RPOs are shown in Figure 3-2. . North Dakota is a member of the Western Regional Air Partnership (WRAP), which serves as the RPO for visibility protection at 118 Class I areas in the 15 western states.

Figure 3-2. Regional Planning Organization Map

⁵ 64 FR 35713

3.1.1 First Implementation Period

The Regional Haze Rule established a schedule setting forth deadlines by which the States must submit their initial regional haze SIPs and subsequent revisions to the SIPs. Regional Haze SIPs for the initial planning period were due in 2007, with subsequent SIP updates due in 2018 and every 10 years thereafter.⁶

Regional Haze SIP requirements for the first planning period required that states incorporate into their plans the core program requirements in 40 CFR 51.308(d), including: (1) establishing reasonable progress goals (RPGs) for each Class I area within the state that provide for measurable progress towards achieving natural visibility conditions; (2) developing a long-term strategy (LTS) including enforceable emissions limitations and compliance schedules to achieve the RPGs; and (3) developing plans to monitor and assess the effectiveness of the LTS to achieve the RPGs over the prior implementation period and affirmation of or revision to the RPGs.

The Regional Haze Rule requires that states determine the consistent rate of progress over time needed to attain natural visibility conditions on the 20 percent most impaired days by the year 2064. This “glidepath” is referred to as the uniform rate of progress (URP) line. States must consider the URP, and the emission reduction measures needed to achieve this level of improvement, when developing their RPGs and LTS. Regulations at 40 CFR 51.308(g) require each state to submit progress reports, in the form of SIP revisions, every 5 years following the submission of the initial SIP. These progress reports must evaluate the progress made towards the RPGs for Class I areas located within the state as well as those Class I areas located outside the state that may be affected by emissions from within the state.

3.1.1.1 Best Available Retrofit Technology

As a one-time requirement during the first implementation period, potential best available retrofit technology (BART) controls had to be evaluated for certain large stationary sources. States were required to conduct BART determinations for “BART-eligible” sources anticipated to cause or contribute to any visibility impairment in one or more Class I area. BART-eligible sources are stationary sources that were put in place between August 7, 1962 and August 7, 1977, and whose operations fall within one or more of the 26 listed source categories, including fossil-

⁶ On January 10, 2017, EPA made a one-time adjustment to the due date for the second implementation period SIPs (2018 – 2028) by extending the deadline from July 31, 2018 to July 31, 2021 (82 FR 3078).

fuel fired boilers of more than 250 MMBtu/hr heat input.⁷ The Riley Boilers fall within the 26 listed source categories, but were not in operation prior to August 7, 1977. In its determination of BART, states were required to take into consideration the costs of compliance, the energy and non-air quality environmental impacts of compliance, any existing pollution control technology in use at the source, the remaining useful life of the source, and the degree of improvement in visibility which may reasonably be anticipated to result from the use of such technology.⁸ As an alternative to requiring source-specific BART controls, states also had the flexibility to adopt an emissions trading program or other alternative program as long as the alternative provided greater reasonable progress towards improving visibility than BART.

3.1.1.2 Reasonable Progress Control Requirements for GPSP during First Planning Period

GPSP commenced operation in 1984, and was not classified as a BART-eligible source or subject to the BART requirements. Nevertheless, during the initial planning period, the NDDH evaluated emissions from the three GPSP Riley Boilers as reasonable progress sources. The reasonable progress analysis prepared by NDDH did not include the Superheaters, flares, or auxiliary combustion sources. The NDDH concluded that no additional controls would be required on the Riley Boilers during the initial planning period and suggested that SNCR or SCR may not be technically feasible NO_x control options.

3.1.2 Second Implementation Period

Second planning period Regional Haze SIPs must be submitted to EPA for review by July 31, 2021. Among other requirements, second planning period SIPs are required to include an assessment of the state's RPGs and LTS. To support states in their efforts to develop the second planning period SIPs, in July 2016 EPA released a draft guidance document titled "*Draft Guidance on Progress Tracking Metrics, Long-term Strategies, Reasonable Progress Goals and Other Requirements for Regional Haze State Implementation Plans for the Second Implementation Period*" ("Draft EPA Guidance").⁹ The Draft EPA Guidance document describes key steps states

⁷ The term "fossil fuel" is generally defined to include natural gas, petroleum, coal, or any form of solid, liquid, or gaseous fuel derived from such material for the purpose of creating useful heat.

⁸ CAA Section 169A(g)(2).

⁹ See, EPA-457/P-16-001. On September 11, 2018, EPA released a "*Regional Haze Reform Roadmap*" announcing its plan to "release a series of implementation tools and guidance documents that will help focus states' efforts and reduce and streamline the time and resources needed to meet the statutory and regulatory requirements for reducing regional haze in National Parks, wildlife refuges, and wilderness areas." EPA stated

should implement when developing their RPGs and LTS for the second implementation period. Key steps identified in the Draft EPA Guidance are listed in Table 3-1.

Table 3-1. Key Steps in Developing Regional Haze SIPs for Second Planning Period

- | | |
|----|---|
| 1. | <i>Ambient data analysis</i> – Quantify baseline, current and natural conditions and the uniform rate of progress that would achieve natural conditions in 2064. (40 CFR 51.308(f)(1)) |
| 2. | <i>Screening of sources</i> – Identify the pollutants and emission sources for which a full reasonable progress analysis will be completed and explain why it is appropriate to limit the full analysis to only these sources. (40 CFR 51.308(f)(2)) |
| 3. | <i>Source and emission control measure analysis</i> – Identify potential emission control measures for sources selected in the screening step and develop data on the four statutory factors and visibility benefits if they will be considered. (40 CFR 51.308(f)(2)) |
| 4. | <i>Decisions on the content of the LTS</i> – Consider applicable factors and decide on new emission controls for incorporation into the LTS. (40 CFR 51.308(f)(2)) |
| 5. | <i>Regional scale modeling</i> – Model the emissions reductions that will result from implementation of the LTS and other enforceable measures that will reduce visibility impairment to set the RPGs for 2028. (40 CFR 51.308(f)(3)) |
| 6. | <i>Progress, degradation and glidepath checks</i> – Demonstrate that there will be an improvement on the 20 percent most impaired days. Demonstrate that there is no degradation on the 20 percent clearest days. Compare the 2028 RPG for the 20 percent most impaired days to the 2028 point on the URP line (the glidepath) and, if required, provide additional justification for the reasonableness of the RPG. Revise the LTS if additional measures are identified as necessary to make reasonable progress. (40 CFR 51.308(f)(3)) |
| 7. | <i>Additional requirements for SIPs</i> – Provide additional information necessary to ensure that other requirements of the Regional Haze rule are met. |

The Draft EPA Guidance recommends that states evaluate all technically feasible emission control options for stationary sources and source categories identified as having the greatest potential to impact visibility at one or more Class I area. The Draft EPA Guidance recommends several options for states to consider when evaluating

that it plans to issue a new guidance document on Regional Haze SIP Development by Spring, 2019. Dakota Gasification Company reserves the right to update and modify this four-factor analysis, as needed, to be consistent with any new guidance issued by the agency.

potential emission reductions, including work practices, replacement and retrofit controls, existing control upgrades, fuel switching, year-round operation of controls, and operating restrictions.¹⁰

Emission control evaluations must consider the four statutory factors identified in 40 CFR 51.308(f)(2)(i) (discussed in Section 3.2). In addition, the Draft EPA Guidance notes that control technology assessment recommendations presented in the BART Guidelines continue to be relevant as recommendations for how a state should evaluate and select emission control measures for stationary sources.¹¹ Recommendations in the BART Guidelines that continue to be relevant to the reasonable progress Four Factor Analysis are listed in Appendix D of the Draft EPA Guidance, and include, in general, the recommended approach for evaluating the technical feasibility, effectiveness, costs, and cost-effectiveness of available emission control measures.¹²

3.2 DESCRIPTIONS OF THE FOUR STATUTORY FACTORS

Under 40 CFR 51.308(f)(2)(i), states must consider four statutory factors when evaluating and determining emissions reduction measures from stationary sources, or groups of sources that are necessary to make reasonable progress towards achieving natural visibility conditions. The four statutory factors are:

1. The estimated cost of compliance;
2. The time necessary for compliance;
3. The energy and non-air quality environmental impacts of compliance; and
4. The remaining useful life of any potentially affected anthropogenic source of visibility impairment.

A brief description of each of the four statutory factors, and EPA's recommendations for evaluating each of the four factors (from the Draft EPA Guidance), is provided below.

3.2.1 Costs of Compliance

Cost estimates should be developed for each technically feasible control option. Costs include the total capital costs to engineer, design, procure, and install the control technology, and annual operating and maintenance (O&M) costs. O&M costs include both fixed and variable O&M. Fixed O&M includes costs that are independent of

¹⁰ See, Draft EPA Guidance, pgs. 85-86.

¹¹ Draft EPA Guidance, pg. 85. The BART Guidelines are published at 40 CFR Part 51 Appendix Y.

¹² Draft EPA Guidance, Appendix D, pgs. 186-196.

control system operation and would be incurred even if the control system were shut down. Fixed O&M includes categories such as operating and maintenance labor, administrative charges, property taxes, and insurance. Variable O&M includes the cost of consumables, including reagent (e.g., lime or limestone, ammonia, urea, etc.), by-product management, water consumption, and electric power requirements associated with operating the control system. For existing facilities, O&M cost estimates should represent the control option's incremental increase over current O&M costs.

Capital costs include all costs required to engineer, design, procure, and install equipment needed for the control system. The Draft EPA Guideline recommends that states adhere to the accounting principles described in Chapter 2 of Section 1 of EPA's Air Pollution Control Cost Manual (the "Control Cost Manual") when calculating control system costs for a four factor analysis.¹³

Section 2.3 of the Control Cost Manual (Section 1, Chapter 2) describes the cost categories generally used to calculate the total capital cost of a retrofit control technology. Cost categories include total capital investment (TCI), which is defined to "include all costs required to purchase equipment needed for the control systems (purchased equipment costs), the costs of labor and materials for installing that equipment (direct installation costs), costs for site preparation and buildings, and certain other costs (indirect installation costs). TCI also includes costs for land, working capital, and off-site facilities." Direct installation costs include costs for foundations and supports, erecting and handling the equipment, electrical work, piping, insulation, and painting. Indirect installation costs include costs such as engineering costs; construction and field expenses (i.e., cost for construction supervisory personnel, office personnel, rental of temporary offices, etc.); contractor fees (for construction and engineering firms involved in the project); start-up and performance test costs (to get the control system running and to verify that it meets performance guarantees); and contingencies.¹⁴

The total annual cost (TAC) of a control option includes the annualized capital recovery cost plus the total annual O&M costs. The Control Cost Manual recommends using an equivalent uniform annual cash flow method to annualize the total capital investment by multiplying the total capital investment by a capital recovery factor

¹³ Draft EPA Guidance, pg.89.

¹⁴ EPA Air Pollution Control Cost Manual, Sixth Edition, EPA/452/B-02-001, January 2002, pg. 2-5.

(CRF).¹⁵ The product of the total capital investment and CRF gives a uniform end-of-year payment necessary to repay the initial capital investment in "n" years at an interest rate of "i". The CRF is calculated using the following equation:

$$CRF = \frac{i * (1 + i)^n}{(1 + i)^n - 1}$$

Where:

i = interest rate; and

n = economic life of the emission control system

The Draft EPA Guidance suggests that states may use generic cost estimates or estimating algorithms for estimating control system costs; however, source specific estimates prepared by knowledgeable engineering professionals provide more reliable information than generic cost estimates.¹⁶ Source-specific cost estimates should be well documented for purposes of public comment and EPA review.¹⁷

The total annual cost of each control option (\$/yr) is divided by the total annual emissions reduction (tpy) to determine the control option's average cost-effectiveness on a \$/ton basis. Emissions reductions are calculated based on the difference between baseline annual emissions and post-control annual emissions. The Draft EPA Guidance generally recommends calculating baseline emissions based on projected 2028 emissions assuming source compliance with emission limits that have been adopted and are enforceable. As an alternative, baseline emissions may be based on representative past actual emissions, assuming there is no evident basis for using a different emissions rate.

3.2.2 Time Necessary for Compliance

For stationary sources, the provisions of the BART Guidelines regarding the time necessary for compliance are relevant to reasonable progress analyses. EPA recommends that prior experiences with the planning and installation of new emission controls is the best guide to how much time a particular source will reasonably need for compliance. However, source-specific factors should be considered when evaluating the time necessary to

¹⁵ Ibid., at pg. 2-21.

¹⁶ Draft EPA Guidance, pg. 91.

¹⁷ Ibid.

engineer, procure, and install an available and technically feasible control option. Source-specific factors that affect the time necessary to install new emission controls should be identified and documented in the Four Factor Analysis.

3.2.3 Energy and Non-Air Quality Environmental Impacts

For stationary sources, the provisions of the BART Guidelines regarding energy impacts are relevant to reasonable progress analyses. Energy impacts of an emission control measure are a matter of engineering design and control system operation; thus, EPA recommends that prior experience at similar sources will be informative. Energy impacts may be considered in terms of kilowatt-hours or fuels used to operate the control system. The energy impact analysis should focus on direct energy consumption at the source rather than indirect energy inputs needed to produce raw materials for the construction and operation of control equipment.

For stationary sources, the provisions of the BART Guidelines regarding non-air quality environmental impacts are relevant to reasonable progress analyses. Non-air quality impacts include solid or hazardous waste generation, increased water consumption, wastewater discharge, land use impacts, and impacts to threatened and endangered species or their natural habitat. Characterizing the non-air quality environmental impacts should be done on a source-specific basis. Other guidance intended for use in assessments under the National Environmental Policy Act may be relevant to this evaluation.

Even though states are not required to consider GHG emission impacts, the Draft EPA Guidance encourages states to consider GHG impacts when developing their LTS.¹⁸ As an example, some measures that would reduce emissions that contribute to visibility impairment will also reduce GHG emissions, such as measures that reduce the use of energy produced from combusting fossil fuels with relatively high GHG emissions. Conversely, control measures that require significant energy to capture visibility impairing emissions could result in increased GHG emissions. Where a measure necessary to make reasonable progress towards natural visibility conditions would increase GHG emissions, Draft EPA Guidance encourages states to work to harmonize visibility and climate change objectives.¹⁹

¹⁸ Draft EPA Guidance, pg. 92.

¹⁹ *Ibid.*

3.2.4 Remaining Useful Life

For stationary sources, the provisions of the BART Guidelines regarding remaining useful life are relevant to reasonable progress analyses. In general, the remaining useful life of the source itself will be longer than the useful life of the emission control measure under consideration unless there is an enforceable requirement for the source to cease operation sooner. Thus, the useful life of the control measure will normally be used in the Four Factor Analysis to calculate emission reductions, amortized costs, and cost-effectiveness. However, if there is an enforceable requirement for the source to cease operation by a date before the end of what would otherwise be the useful life of the control measure under consideration, then the enforceable shutdown date should be used to calculate remaining useful life and evaluate control technology cost-effectiveness.

3.2.5 Four Factor Analysis Approach

S&L used a top-down approach to identify and evaluate the technical feasibility and effectiveness of potentially available SO₂ and NO_x control measures. S&L followed Steps 1 through 3 of the top-down approach described in the BART Guidelines to identify all available retrofit emission control measures, eliminate technically infeasible options, and evaluate the effectiveness of the technically feasible options. A brief description of each step is provided below.

Step 1 - Identify All Available Control Options

Available control options are those air pollution control technologies with a practical potential for application to the emission unit and the regulated pollutant under evaluation. Air pollution control technologies can include a wide variety of available methods, systems, and techniques for control of the affected pollutant, and include not only existing controls for the source category but also take into account technology transfer of controls that have been applied to similar source categories and gas streams. Technologies which have not been applied to (or permitted for) full scale operations need not be considered as available.

In an effort to identify all potentially available emission control technologies, S&L searched a broad range of information sources including, but not necessarily limited to:

- EPA's RACT/BACT/LAER Clearinghouse (RBLC);
- EPA's New Source Review (NSR) and Clean Air Technology Center (CATC) Web sites;

- BART evaluations prepared during the initial Regional Haze planning period;
- Information from control technology vendors and engineering/environmental consultants;
- Federal and State NSR permits and Best Available Control Technology (BACT) determinations for similar sources; and
- Technical journals, reports, newsletters, and air pollution control seminars.

Step 2 - Eliminate Technically Infeasible Control Options

In Step 2, S&L evaluated the technical feasibility of the control options identified in Step 1 with respect to source-specific and unit-specific factors. Control technologies are technically feasible if either: (1) they have been installed and operated successfully for the type of source under review under similar conditions; or (2) the technology could be applied to the source under review. In order for a control option to be technically feasible, it must be “available” and “applicable” to the source under consideration. A technology is considered “available” if the source owner may obtain it through commercial channels. An available technology is “applicable” if it can reasonably be installed and operated on the source type under consideration.

Control technologies that are technically infeasible (i.e., not available or not applicable to the source under consideration) are eliminated from further evaluation. A demonstration of technical infeasibility must be based on physical, chemical, and/or engineering principals, and must show that technical difficulties would preclude the successful use of the control option on the emission unit under consideration. The economics of an option are not considered in the determination of technical feasibility/infeasibility.

Step 3 - Evaluate Technically Feasible Control Technologies for Effectiveness

Step 3 involves evaluating the control effectiveness of all the technically feasible control alternatives identified in Step 2 for the pollutant and emissions unit under review. Control effectiveness should be expressed using a metric that ensures an “apples-to-apples” comparison of emissions performance levels among options, and is generally expressed as the rate that a pollutant is emitted after installation of the control measure. Control technology evaluations for existing sources should consider ways to improve the performance of existing control devices. Special circumstances pertinent to the specific unit under review should be identified and taken into consideration when assessing the capability of the control alternative and determining control effectiveness.

For this evaluation, S&L assessed the technically feasible SO₂ and NO_x control options for effectiveness on various sources at the GPSP facility, including the Riley Boilers, Superheaters, Package Boiler, Main Flare, and Startup Flare.

4. BASELINE SO₂ AND NO_x EMISSIONS

The first step in developing the Four Factor Analysis is to establish the baseline SO₂ and NO_x emissions for the Riley Boilers, Superheaters, Package Boiler, Main Flare, and Startup Flare. Different averaging periods were used to determine representative emissions for each of the sources due to the variability in the nature of their operation.

To establish representative baseline emissions, S&L evaluated Riley Boiler and Superheater operating data for the period January 1, 2016 to September 30, 2018 to identify periods of normal operation (i.e., periods of operation when the boiler was not limited by infrequent or extraordinary operating restrictions). Based on review of fuels consumed, heat input, emissions control systems in place, as well as input from DGC, it was determined that this entire period was representative of normal operation for the Riley Boilers and Superheaters. The maximum 24-consecutive month annual average emission rate during the representative time period was used to establish baseline annual emissions (in terms of tons per year [tpy]) for the three Riley Boilers combined and the two Superheaters combined.

Baseline annual SO₂ and NO_x emissions for the Riley Boilers and Superheaters were determined based on data obtained from the GPSP continuous emission rate monitoring systems (CERMS) and emissions calculations that the facility uses to report to the NDDH. While the Riley Boiler and Superheater flue gases are routed to a common stack, the NDDH has referred to them as separate emission sources. As such, the three Riley Boilers will be evaluated as a single source and the two Superheaters will be evaluated as a single source. Since the Riley Boilers and Superheaters combine to a single stack, the stack SO₂ CERMS and reheat duct process monitor operating data were evaluated to determine the emissions generated from the Riley Boilers and the Superheaters. Stack NO_x CERMS and flue gas test reports were used to determine the emissions generated between the Riley Boilers and the Superheaters.

S&L also evaluated the GPSP Package Boiler emissions data for the baseline period of December 20, 2017 through October 11, 2018. Less than a full year of data is available since the unit only recently came into service; therefore, the total heat input was scaled to estimate the total expected annual heat input. S&L and DGC determined that the baseline operating period was representative of normal operation for the Package Boiler and encompasses operation of the ULNB system for NO_x control. Since a full year of operation has not occurred at the time of this evaluation,

the maximum 30-day rolling annual average emission rate during the representative baseline period was used to establish baseline annual emissions (in tpy) for the Package Boiler.

S&L evaluated the Main Flare and Startup Flare monthly emissions data for the representative period January 1, 2015 through October 31, 2018 to determine periods of normal operation. Since the facility's flares do not have a prescribed normal operating condition, it was determined that all operation during the baseline time period was representative of typical operation. As such, to determine a realistic emission rate, the maximum annual average emission rate calculated during the representative time period was used to establish baseline annual emissions (in tpy) for the Main Flare and the Startup Flare.

Using the baseline annual average emissions and the respective baseline heat inputs described above for each source, representative emissions in terms of lb/hr were developed. Table 4-1 provides a summary of the GPSP SO₂ and NO_x representative baseline emissions for each source. Additional details are included in Appendix B.

Table 4-1. Baseline Emissions

Source	Pollutant	Baseline Controls	Emissions		Heat Input	Notes
			lb/hr	tpy	MMBtu/yr	
Three (3) Riley Boilers	SO ₂	WFGD	671	2757	13,691,041	SO ₂ emissions based on 24-month annual average tpy for period January 1, 2016 – December 31, 2017
	NO _x	Combustion tuning, LNB & OFA	517	2260	14,265,939	NO _x emissions based on 24-month annual average tpy for period August 18, 2016 – August 17, 2018
Two (2) Superheaters	SO ₂	Low-sulfur fuel	56	246	1,971,982	Emissions based on 24-month annual average tpy for period May 1, 2016 – April 30, 2018.
	NO _x	Combustion tuning, FGR & LNB	44	194	1,971,982	
Package Boiler	SO ₂	Low-sulfur fuel	Non-detect	Non-detect	1,265,958	Emissions based on maximum 30-day rolling annual average for period December 20, 2017 – October 11, 2018. Annual emissions and annual heat input based on assuming similar operation for 12 months of the year to develop tpy.
	NO _x	ULNB	4	19	1,265,958	
Main Flare	SO ₂	n/a	75	327	2,462,437	Emissions based on annual average emission rate tpy for 2018.
	NO _x	n/a	24	105	3,523,823	Emissions based on annual average emission rate tpy for 2015.
Startup Flare	SO ₂	n/a	17	74	363,233	Emissions based on annual average emission rate tpy for 2015.
	NO _x	n/a	3	12	363,233	

5. RILEY BOILER CONTROL MEASURES

5.1 SO₂ EMISSIONS CONTROLS

In 1996, an ammonia-based WFGD system was installed on the Riley Boilers, and has been providing SO₂ reduction. Outside of startup, shutdown, maintenance, or malfunction, the single WFGD system is designed to treat 100% of the flue gas from the three Riley Boilers. During normal operation, the WFGD most often operates at 97-98% SO₂ removal efficiency across the absorber.

As part of the first planning period for Regional Haze, the NDDH concluded that Riley Boiler WFGD system is comparable to BACT or BART for industrial boilers of similar size.²⁰ Since its installation in 1996, limited improvements in the industry have been made to provide over 98% removal efficiency on ammonia-based scrubbers, especially on inlet rates over 10 lb SO₂/MMBtu. Furthermore, as indicated in the Draft EPA Guidance, operation of WFGD at 97-98% removal efficiency is similar to the levels expected from advanced FGD systems.²¹ Since the WFGD is operating at BACT levels and is considered an advanced FGD system, SO₂ controls will not be evaluated further for the Riley Boilers.

5.2 NO_x EMISSIONS CONTROLS

The Riley Boilers are regularly tuned to optimize combustion and are equipped with low-NO_x burners (LNB), and a pseudo-overfire air (OFA) windbox. The Riley Boilers underwent upgrades to their firing systems and combustion air systems in 2000. Specifically, the boilers were upgraded with windbox partition plates, burner air supply dampers with pneumatic rotary actuators, air monitor probes, six staged fuel tips for synthetic natural gas (SNG) guns, six tar oil atomizers, and six tar oil meter valves. By diverting a majority of the combustion air to the windbox, the main combustion zone temperature is lowered, which lowers the thermal NO_x formation in the combustion zone. The purpose of this pseudo-OFA upgrade was to optimize performance of the boilers and reduce NO_x emissions. The flow measuring devices allow for consistent fuel-to-air ratios at each individual burner location within the furnace. NO_x formation is optimized by monitoring and controlling fuel-to-air ratios throughout

²⁰ North Dakota Regional Haze SIP, pg. 183.

²¹ Draft EPA Guidance, pg. 87.

combustion zones within the furnace. Finally, upgrades to the burners themselves with staged fuel tips creates a gradient of fuel-rich and fuel-lean zones within the burners, which further reduces NO_x formation.

5.2.1 Identify Available NO_x Control Options

After establishing baseline emissions for the source being evaluated, S&L reviewed the available NO_x control options. Available control options are those air pollution control technologies and operational measures with a practical potential for application to the emission source and the regulated pollutant under evaluation. Based on a review of available NO_x control technologies installed on existing liquid- and gas-fired boilers, as well as operational practices and equipment upgrades implemented on existing control systems, the potentially available options to control NO_x emissions from the GPSP Riley Boilers are listed in Table 5-1.

Table 5-1. Available NO_x Control Options

NO _x Control Technologies
Combustion Optimization
Flue Gas Recirculation (FGR)
Selective Non-Catalytic Reduction (SNCR)
Selective Catalytic Reduction (SCR)

5.2.2 Technical Feasibility of Available NO_x Control Options

Potentially available NO_x control options identified in Table 5-1 were evaluated for technical feasibility (i.e. availability and applicability to the GPSP Riley Boilers) based on a review of physical, chemical, and engineering principals, and an assessment of commercial availability. Options deemed to be technically infeasible, or options that have no practical application to the evaluated source, were eliminated from further review. S&L evaluated the effectiveness of the control options determined to be technically feasible and established an emission performance level (i.e., controlled emission rate) for each.

5.2.2.1 Combustion Optimization

Combustion optimization methods using online analyzers have been developed to improve boiler performance through implementation of artificial intelligence concepts (e.g., neural networks). These control strategies are

capable of setting target objectives, like NO_x output, and adjusting multiple input variables to meet these target objectives. Neural networks have the ability to connect inputs and objectives based on continuous monitoring of plant information. These systems will automatically adjust digital control system (DCS) parameters in real time by implementing bias and trim settings on pressures, temperatures, and flows that result in the optimal boiler performance for the parameter(s) being controlled. Combustion optimization programs are meant to act as an automated real-time boiler tuning mechanism, rather than manual tuning. Depending on the complexity of the system to which it is applied and on the quality of DCS installed at a facility, the improvement in boiler efficiency can be significant. A side-effect of improved boiler efficiency is a potential improvement in NO_x emissions.

Operation of the Riley Boilers is significantly more involved than typical single- or dual-fired boilers. The boilers are required to adapt to upsets and changes in product and fuel production rates, especially with gaseous fuel production since it cannot be stored. Boiler fuel sources are dictated by the gasification process conditions, requiring the boilers to adjust quickly to changes in fuel inputs. With seven different fuels injected at various elevations within the boiler, it is difficult to maintain steam production quality and quantity, as well as optimize combustion temperatures and oxygen concentrations. Furthermore, fuel quality alters as the gasification process conditions change.

Attempts to operate the Riley Boilers, and other combustion sources, in automatic mode has caused detrimental impacts to steam production rates to a complex steam system with 11 different grades of steams and multiple steam uses, which all require different flow rates and steam qualities. Operators are needed to manually adjust the steam production rates between the Riley Boilers, Superheaters, and Package Boiler to maintain the steam balance in real-time for the entire facility. As such, fine tuning of the fuel flow rates and locations within the Riley Boilers on an automatic basis is unlikely to provide consistent NO_x reduction while being able to maintain fuel firing flexibility and steam production quality and quantity. Furthermore, the primary purpose of neural networks and combustion optimization systems are to improve boiler efficiency rather than reduce emissions. Neural network original equipment manufacturers (OEMs) often suggest a potential reduction in NO_x emissions, but typically do not provide a guaranteed emissions reduction.

For these reasons, on-line combustion optimization is not considered a technically feasible NO_x reduction technology for the Riley Boilers and will not be evaluated further.

5.2.2.2 Flue Gas Recirculation (FGR)

Flue Gas Recirculation (FGR) is a method of NO_x control in which the flue gas produced in the boiler is directed back into the furnace via the primary combustion zone in the windbox. The flue gas is mixed with the combustion air and enters the boiler via the burners. The reused flue gas both limits the amount of oxygen at the burners and cools the combustion temperature, which reduces NO_x formation. The two major challenges to implementing FGR on existing boilers are maintaining flame stability and retaining steam temperatures.

FGR is a proven technology which has been implemented in the industry over various applications, but most often in single-fuel-fired boilers (e.g., natural gas boilers). Because boiler furnaces are initially engineered for precise combustion conditions, major modifications like FGR pose challenges in implementation and troubleshooting. FGR systems also often require significant modifications in ductwork, supports, boiler tuning, and operations. There are concerns regarding the application of an FGR system at the GPSP Riley Boilers due to the use of both liquid and gaseous fuels and the variation in fuel flows and heat inputs. As the process dictates, fuels will change drastically in the firing rates as well as location of firing within the boiler, which will cause swings in combustion temperatures and boiler O₂. The variation in the fuel firing rate will require precise operation of FGR to ensure the FGR ratio is maintained throughout all operating regimes.

DGC has received proposals for FGR systems on the Riley Boilers for additional NO_x control. In 1999, Applied Utility Systems Inc. (AUS) proposed a retrofit of FGR technology on all three Riley Boilers. However, further investigation determined that the FGR system would not provide any additional NO_x reduction since the Riley Boilers fire waste gas, which is predominantly CO₂. AUS suggested that the waste gas fired at DGC, which contains a substantial amount of inert compounds, quenches the flame as it is combusted and reduces the amount of thermal NO_x formation, which is typically the largest contributor to NO_x emissions. The OEM suggested that as long as waste gas continues to be fired in the boilers, the potential for NO_x reduction using FGR is limited and impractical. At this time, the facility already receives the benefits similar to an FGR system. Therefore, FGR is not considered a technically feasible option for additional NO_x control on the Riley Boilers and will not be evaluated further.

5.2.2.3 Selective Non-Catalytic Reduction

Selective non-catalytic reduction (SNCR) involves the direct injection of ammonia (NH₃) or urea ((NH₂)₂CO) at high flue gas temperatures (approximately 1,600°F – 2,100°F) in an oxidizing environment. The ammonia or urea reacts with NO_x in the flue gas to produce N₂ and water as shown below.

Flue gas temperature at the point of reagent injection can greatly affect NO_x removal efficiencies and the quantity of NH₃ or urea that will pass through the SNCR unreacted (referred to as NH₃ slip). In general, SNCR reactions are effective in the range of 1,600°F – 2,100°F. At temperatures below the desired operating range, the NO_x reduction reactions diminish and unreacted NH₃ emissions increase. Above the desired temperature range, NH₃ is oxidized to NO_x resulting in low NO_x reduction efficiencies.

Mixing of the reactant and flue gas within the reaction zone is an important factor to SNCR performance. In large boilers, the physical distance over which reagent must be dispersed increases, and the surface area/volume ratio of the convective pass decreases. Furnace geometry, urea spray coverage, and droplet size must be considered when developing good mixing of reagent and flue gas, injecting reagent in the proper temperature window, and ensuring sufficient residence time of the reagent and flue gas in that temperature window. As the boiler cycles in load, the optimum injection region may change; thus, most facilities require multiple injection zones which are placed in and out of service as the unit ramps in load. This can include modifying the zones of injectors that are operating at different fuel inputs and temperatures.

In addition to temperature and mixing, several other factors influence the performance of an SNCR system, including residence time, reagent-to-NO_x ratio, and fuel sulfur content. Increasing the normalized stoichiometric ratio (NSR) can improve NO_x removal.²² This can be achieved by increasing urea solution flow through the injectors or changing the concentration of urea in the solution. However, too high of reagent injection rates will

²² NSR defines the amount of reagent needed to achieve the targeted NO_x reduction. Based on the reaction equations in 5.2.2.2, two moles of NO_x can be removed with one mole of urea or two moles of ammonia. In practice, more than the theoretical amount of reagent needs to be injected into the boiler flue gas to obtain a specific level of NO_x reduction. This is due to the complexity of the actual chemical reactions involving NO_x and injected reagent and mixing limitations between reagent and flue gas. Factors that influence the NSR value: (1) percent NO_x reduction; (2) uncontrolled NO_x concentration in the flue gas; (3) temperature and residence time available for the NO_x reduction reactions; (4) extent of mixing achievable in the boiler; and (5) allowable ammonia slip.

increase the ammonia slip. Ammonia remaining in the flue gas past the reaction window will cause issues with downstream components, especially if the sulfur concentrations in the flue gas are high. For typical boilers, 10 ppm ammonia slip is the maximum recommended amount for SNCR operation, due to formation of ammonia salts, which can cause corrosion.

One significant drawback of ammonia-based NO_x control systems is the undesired side-reaction of ammonium sulfate and ammonium bisulfate (ABS). The reaction mechanism is carried out as shown below:

These reactions take place when unreacted ammonia from the SNCR process comes in the presence of sulfur trioxide (SO₃) compounds. The reaction carries out more readily as the temperature lowers within the process. ABS deposits out of the flue gas as a sticky liquid and will foul the inside of ductwork and within open spaces in equipment along the flue gas pathway.

While SNCR can be applied to various types of boilers, NO_x reduction potential is specific to the temperature windows and residence time. Oftentimes, the reagent utilization, and subsequent ammonia slip rates, is the limiting factor for NO_x reduction potential.

In September and October of 1997 DGC tested the injection of aqueous ammonia into Riley Boiler B. Ammonia solution was introduced into two separate zones of the boiler to partially simulate operation of an SNCR system. After a week of testing the ammonia system, the Riley Boiler experienced economizer leakage, high furnace pressure, and loss of outlet air flow. An investigation revealed the source of the furnace pressure buildup was due to buildup of ammonium sulfate on the Ljungström air pre-heater baskets. Results of the testing were inconclusive, as the main stack CEMS was utilized for determining impact to NO_x, and four other emission sources that fire into the main stack were in operation during the testing.

During a second test run, a rental NO_x analyzer was used to isolate NO_x emissions reductions during ammonia injection in the Riley B Boiler. The results of this test showed 3-5% reduction in NO_x emissions. D.B. Riley, the boiler and SNCR OEM, provided new spray nozzles and the average NO_x reduction improved to 17%. Eventually, the boiler experienced similar issues with economizer leakage, low outlet flow, high furnace pressure, and plugging

of the air pre-heater with ammonium sulfate after a few days of testing. Ammonium sulfate generation was likely due to the high sulfur content of the fuels fired in the Riley Boilers combined with ammonia slip from the SNCR process. The operators noticed significant buildup of ammonia salts on the air heater baskets, which causes corrosion and added pressure drop. Ammonium sulfate can also deposit on boiler tubes, which will cause issues with the process steam production. The facility witnessed ammonia salt formation on the boiler tube banks during testing, which reduces heat transfer efficiency. While many utilities can still operate with reduced steam quality, at the cost of a partial derate, the reduction in steam quality at GPSP may eliminate the possibility of using the steam in all locations it is needed within the facility and limit the total production rate of the facility. Because of the consistent operational failures, the ammonia system was abandoned in place, and removed years later. The conclusion of the ammonia injection project was that high levels of SO₂ in the gasification facility's produced fuels were the main contributor to the formation of the ammonium salts.

The formation of ammonium sulfate and ABS salts is a problem experienced by plants with high ammonia slip, high sulfur levels, and reduced temperature windows near the air preheaters. The unique operational configuration and fuels combusted by the Riley Boilers exacerbates sulfate salt formation by introducing unpredictable variations in sulfur content to the boiler furnace over time. This can lead to significant ABS formation, and therefore air preheater plugging and boiler malfunction, which was noticed in a short SNCR trial. For these reasons, the NDDH suggested in the first planning period that SNCR is not a technically feasible NO_x control technology on the Riley Boilers. At the very least, the NDDH concluded that pilot scale testing would be needed to determine the feasibility of SNCR application on a high sulfur flue gas.²³ Because of the site's historical issues with ammonia injection, SNCR technology is not considered a technically feasible option for the Riley Boilers and will not be evaluated further.

5.2.2.4 Selective Catalytic Reduction

SCR is a process by which ammonia reacts with nitric oxide (NO) and nitrogen dioxide (NO₂), collectively NO_x, in the presence of a catalyst to reduce the NO_x to nitrogen (N₂) and water. SCR technology has been applied to NO_x-bearing flue gases generated from solid-, liquid-, and gas-fired facilities burning various types of fuels. S&L is unaware of any instances where SCR has been implemented on a boiler that burns gasification products. However,

²³ North Dakota Regional Haze SIP, February 24, 2010, pg. 184.

it can be considered similar to other liquid- and gas-fired boilers when considering flue gas conditions and NO_x composition, where SCR has been considered appropriate. The principal reactions resulting in NO_x reduction are:

Because these reactions proceed slowly at typical boiler exit gas temperatures, a catalyst is used to increase the reaction rate between NO_x and ammonia. Depending on the specific constituents in the flue gas, a typical temperature range of 550°F to 780°F is necessary to achieve normal performance of the catalyst; however, the low end of the temperature window is dependent on the sulfur concentration of the flue gas, due to the lower formation temperature with higher sulfur presence. Therefore, many facilities with high sulfur fuels require a minimum operating temperature closer to 700°F to reduce the potential of localized ammonium salt formation.

SCR catalyst deactivation occurs through two primary mechanisms: physical deactivation and chemical poisoning. Physical deactivation is caused by either exposure of the catalyst to excessive temperatures (thermal deactivation) or masking of the catalyst due to entrainment of particulate from the flue gas stream (fouling). Chemical deactivation is caused by either an irreversible reaction of the catalyst with a contaminant in the gas stream (poisoning) or a reversible absorption of a contaminant on the surface of the catalyst (inhibition). Loss of catalyst activity through thermal degradation or poisoning is permanent, and reactivity can only be restored by replacing the catalyst.

SCR catalyst poisoning is expected to result from the presence of trace elements and strong alkaline substances in flue gas, including sodium (Na), potassium (K), magnesium (Mg), and calcium (Ca). Alkaline metals can chemically attach to active catalyst pore sites and cause deactivation. Sodium and potassium are of prime concern, especially in their water-soluble forms, which are more mobile and can penetrate into the catalyst pores. Earth metals, especially calcium, can react with SO₃ absorbed within the catalyst to form CaSO₄ and blind the catalyst. The North Dakota lignite fuel gasified at GPSP contains relatively high levels of organically associated alkali and alkaline-earth elements, including Na, K, Mg, and Ca. While these components are not tracked in the fuels fired in the boiler, it is expected that the alkali metals will concentrate in the liquid fuels fired in the boiler (e.g., tar oil, N/P), analogous to the relatively high concentration of mercury measured in the liquid fuels in comparison to the feedstock lignite at the facility. It is expected that other metals, such as alkali earth metals, would follow a similar

path of volatilization in the gasifier and condensation in the water-gas-shift reaction, cooling train, and Rectisol unit.²⁴

Traditionally, SCR application on coal-fired boilers is in a high-dust configuration, where the SCR reactor is located in the flue gas stream between the economizer outlet and the air heater inlet. This configuration locates the SCR within the inherently optimal temperature range environment for NO_x reduction (i.e., 650°F to 750°F); however, the high fly ash loading at the economizer outlet can also have detrimental effects on the SCR catalyst. In a low-dust configuration, the SCR reactor vessel is located in the flue gas stream (e.g., downstream of WESP). In the case of GPSP's Riley Boilers, only gaseous and liquid fuels are fired, resulting in an inherently low-dust environment between the economizer and air preheater. The lack of fly ash particles is beneficial in reducing potential for erosion and pluggage of catalyst; however, employing this configuration is expected to expose the catalyst to potentially high levels of vapor-phase alkalis, such as sodium, which is expected to be concentrated in the tar oil produced from North Dakota lignite fuel. It is expected that the metals are concentrated in the liquid fuels (e.g., tar oil, N/P) rather than leaving the gasification system through other means (e.g., SNG, urea, etc.). The high concentration of alkalis immediately downstream of the boiler may preclude the applicability of low-dust SCR catalyst functionality. As such, both the high-dust and low-dust SCR configurations are not considered technically feasible NO_x control options and will not be evaluated further.

In the tail-end configuration for the Riley Boilers, the SCR reaction vessel would be located in the flue gas stream after the FGD control system. The potential advantage of a tail-end SCR (TE-SCR) configuration at GPSP is that the flue gas from the Riley Boilers will have passed through the WFGD system prior to the SCR catalyst. As such, there is the possibility that the mass transfer mechanism that results in the capture of SO₂ will also capture some of the vapor-phase alkali particles, reducing the risk of catalyst poisoning and/or deactivation.

Operation of the tail-end configuration would require significant heating to raise the temperature of the flue gas to the activated temperature range of the SCR catalyst, to at least 550°F. Successful operation of the tail-end configuration would require a gas-to-gas heat exchanger to reheat the flue gas to support the SCR NO_x reactions.

²⁴ The water-gas-shift reaction utilizes water to convert CO into CO₂ and H₂. After the gas is shifted, it enters a cooling train, where process cooling water is used to chill the shifted gas and condense tar components. The gas then is subcooled prior to the Rectisol unit, where it is treated to further remove sulfurous compounds and CO₂ with a solvent. These consecutive process islands all provide mechanisms for alkalis and other metals to condense into the liquid fuels (e.g., tar oil, N/P).

Installation of the SCR downstream of the reheat duct tie-in would be advantageous due to the higher temperature flue gas; however, this option is not technically feasible due to the potential presence of alkalis, as will be discussed further in Section 6.2.2.3. Due to the presence of residual SO_3 at the WFGD and WESP outlet, the formation of ABS is of concern. As such, an additional in-duct heating element should be employed to raise the SCR inlet temperature to 600°F, using SNG-fired duct burners. After the flue gas passes through the SCR (at approximately 600°F), it would pass through the hot side of the gas-to-gas heat exchanger to recover the heat and cool the flue gas prior to combining with the reheat duct upstream of the stack.

TE-SCR has not been demonstrated on a unit similar to the Riley Boilers in which solid-derived fuels are fired. There are also concerns of the remaining SO_2 in the flue gas reacting with the ammonia slip from the SCR and forming ABS on the gas-to-gas heat exchanger tubes. Furthermore, a percentage of the SO_2 remaining in the flue gas will oxidize to SO_3 as it passes through the SCR catalyst, potentially requiring additional SO_3 controls on the source upstream of the SCR. To mitigate SO_3 increases, dry sorbent injection could be required. However, the introduction of a calcium or sodium sorbent upstream of the WFGD will result in additional calcium- or sodium-based sulfur byproducts in the ammonia sulfate solids. It is assumed that this combination will result in loss of sales of the ammonia sulfate fertilizer. As such, cost is included to reflect loss of sales and increased waste disposal costs. Currently, the landfill permit only allows a small amount of ammonium sulfate disposal; as such, if all of the WFGD byproduct is disposed in the landfill, the current solid waste disposal permit or landfill designation will require modification.

In general, catalyst in a TE-SCR will still be vulnerable to alkali poisoning, pore pluggage, and premature catalyst deactivation, and it is not known whether the comparatively high levels of soluble sodium and potassium in North Dakota lignite will be effectively removed by the upstream WFGD. In order to understand the applicability of installing an SCR on gasification product-fired boilers or the effect of North Dakota lignite-derived flue gas on the SCR catalyst, identify potential design solutions, and evaluate the technical feasibility and effectiveness of TE-SCR with any degree of certainty, pilot scale testing of the control configuration would be needed. Since there has not been a similar application of SCR on similar fuels or boiler configurations, extended trials would be needed to better understand the design and operation of a TE-SCR at GPSP. Because there are unresolved issues associated with catalyst poisoning, it is unlikely that DGC could obtain a viable commercial offering for TE-SCR at the GPSP facility. Furthermore, during the initial planning period, NDDH suggested there were concerns regarding technical feasibility of SCR as a NO_x control technology at GPSP and pilot scale testing would be required to determine

feasibility.²⁵ In the years following the initial planning period, during the BART analysis for other North Dakota boilers, TE-SCR was considered technically infeasible based on the lack of vendor guarantees and need for pilot testing.²⁶ However, since cost data was developed by the NDDH in the first planning period, it will be carried forward in the Four Factor Analysis to evaluate hypothetical cost effectiveness.

S&L assumed that the TE-SCR control option could achieve 80% removal efficiency on average on the Riley Boilers, for a controlled NO_x emission rate of approximately 103 lb/hr.

5.2.2.5 NO_x Control Summary

Table 5-2 summarizes the results of the feasibility evaluation of available control options for the GPSP Riley Boilers.

Table 5-2. Summary of Technically Feasible NO_x Control Options – Riley Boilers

NO _x Control Option	Technically Feasible (Yes/No)	Technical Feasibility Summary
Combustion Optimization	No	Implementation of on-line combustion optimization is not considered a technically feasible control option for the GPSP Riley Boilers due to the unique operating requirements to maintain steam conditions and flexibility in fuel firing.
Flue Gas Recirculation	No	Flue Gas Recirculation (FGR) is not considered a technically feasible control option for the GPSP Riley Boilers due to the fuel firing profile (e.g., waste gas) which results in similar combustion flame temperature and oxygen content as traditional FGR.
Selective Non-Catalytic Reduction (SNCR)	No	SNCR is not considered a technically feasible NO _x control technology for the GPSP Riley Boilers. Historic tests preclude the viability of SNCR operation on the Riley Boilers at GPSP due to significant issues with air preheater pluggage and boiler tube deposits.
Tail-end Selective Catalytic Reduction (TE-SCR)	No*	TE-SCR installation on the Riley Boilers would be a first-of-a-kind installation on a boiler firing North Dakota lignite gasification products. Further, extensive testing would be required to determine the impact of alkalis on deactivation of SCR catalyst on the North Dakota lignite-derived fuels fired at GPSP. Because there are unresolved issues associated with catalyst poisoning, it's unlikely that DGC could obtain a viable commercial offering for TE-SCR on the Riley boilers. *TE-SCR will be carried forward to the Four Factor Analysis to present hypothetical costs since the Department included it in the reasonable progress analysis for GPSP during the first planning period.

5.2.3 Effectiveness of NO_x Control Options

The NO_x control technologies that are evaluated as part of the Four Factor Analysis are listed in Table 5-3 in descending order of control efficiency. Table 5-3 also provides control option-specific NO_x emission rates in terms of lb/hr. Emission rates shown in Table 5-3 represent average emission rates that the control options would be expected to achieve during normal operations on a long-term annual basis.

Table 5-3. Effectiveness of NO_x Control Options – Riley Boilers

Control Technology	NO _x Emission Rate ^(Note 1) lb/hr	% Reduction from Baseline Emission Rate
Selective Catalytic Reduction (tail-end) ^(Note 2)	103	80%
Baseline (Combustion Optimization / OFA / LNB)	517	--

Note 1. Emission rates shown represent average emission rates that the control options would be expected to achieve on an ongoing long-term basis under normal operating conditions for GPSP Riley Boilers. Emission rates are provided for comparative purposes, and should not be construed to represent proposed emission limits. Corresponding permit limits must be evaluated on an emission source type and control system-specific basis.

Note 2. TE-SCR has not been installed on a North Dakota lignite-fired unit or lignite-derived-fuel unit, and extended trials would be needed to better understand the design and operation of TE-SCR on the GPSP Riley Boilers. Nevertheless, during the initial planning period, NDDH evaluated the costs and cost-effectiveness of the control system on the Riley Boilers. TE-SCR will, therefore, be carried forward to the Four Factor Analysis to present hypothetical costs since the Department included it in the reasonable progress analysis for GPSP during the first planning period; however, technical feasibility has never actually been demonstrated for TE-SCR for lignite-based fuels.

6. SUPERHEATER CONTROL MEASURES

6.1 SO₂ EMISSIONS CONTROLS

The Superheaters at the GPSP currently fire a mixture of SNG and tar oil. The exhaust from Superheaters A and B are combined into a reheat duct, which heats the Riley Boiler WFGD outlet stream above the dew point prior to being routed up the main stack.

Annual SO₂ emissions from the Superheaters are minimized by firing a blend of SNG and tar oil, with a higher percentage of SNG being fired. The Superheaters typically fire between 80-90% SNG; repeated fuel samples of the SNG show that sulfur composition is non-detectable. The majority of sulfur is introduced into the Superheaters through the firing of tar oil.

On average, the Superheaters account for 13% of the total baseline heat input to the Main Stack. In addition, the Superheaters contribute an insignificant amount of SO₂ (on average less than 10%) emissions to the Main Stack SO₂ emissions for the same time period. Furthermore, due to the efficiency of the WFGD on the Riley Boilers and minimal SO₂ generated in the Superheaters, 96% of the SO₂ generated by the Riley Boilers and Superheaters does not reach the stack, as shown in Table 6-1.

Table 6-1. Comparison of Baseline SO₂ Emissions

	Units	Riley Boilers (Baseline)	Superheaters (Baseline)	Main Stack (Baseline)
Uncontrolled SO ₂ Emissions	tpy	19,905	56	19,961
Stack SO ₂ Emissions	tpy	671	56	727
SO ₂ Removal Rate	%	97	0	96

One potential option for further SO₂ reduction from the Superheaters would be changing the firing profile of the tar oil and SNG so that the SNG firing is at its maximum; however, the facility needs to maintain flexibility to fire up to 100% tar oil to provide process relief during unexpected tar oil production rates or system buildup. While the Superheaters are designed to fire up to 100% tar oil, GPSP typically fires a high percentage of SNG that in turn minimizes SO₂ emissions. As a result, there is no additional opportunity to reduce the amount of tar oil that is fired

without removing the facility’s needed flexibility. As such, there are no technically feasible options to reduce SO₂ emissions from the GPSP Superheaters.

6.2 NO_x EMISSIONS CONTROLS

Superheaters A and B are equipped with LNB and FGR for NO_x control. The LNBs are John Zink burners designed for axial flow combustion. Combustion air flow is evenly distributed to the burners by baffles within the windbox. The airflow is diverged into primary air, air that flows through the swirler and angularly outward from the burner centerline, and secondary air, which passes outside the periphery of the swirler and reacts with the unburned fuel to complete the combustion process. FGR technology is also implemented for the Superheaters, in which a portion of the flue gas is reintroduced to the burners to lower combustion temperatures and oxygen concentrations.

During the plant modifications in 2000, two-stage fuel tar oil atomizers were installed to provide highly efficient liquid fuel distribution to each burner within the Superheaters, resulting in reduction in overall NO_x formation.

6.2.1 Identify Available NO_x Control Options

Based on a review of available NO_x control technologies installed on existing sources, as well as operational practices and equipment upgrades implemented on existing control systems, potentially available options to control NO_x emissions from the GPSP Superheaters are listed in Table 6-1.

Table 6-2. Available NO_x Control Options

NO _x Control Technologies
Combustion Optimization
Selective Non-Catalytic Reduction (SNCR)
Selective Catalytic Reduction (SCR)

6.2.2 Technical Feasibility of Available NO_x Control Options

Potentially available NO_x control options identified in Table 6-1 were evaluated for technical feasibility (i.e. availability and applicability to the GPSP Superheaters) based on a review of physical, chemical, and engineering principals, and an assessment of commercial availability. Options deemed to be technically infeasible, or options that have no practical application to the evaluated source, were eliminated from further review. S&L evaluated the

effectiveness of the control options determined to be technically feasible, and established an emission performance level (i.e., controlled emission rate) for each.

6.2.2.1 Combustion Optimization

Combustion optimization methods using online analyzers have been developed to improve boiler performance through implementation of artificial intelligence concepts (e.g., neural networks). These control strategies are capable of setting target objectives like NO_x output, and adjusting multiple input variables to meet these target objectives. Neural networks have the ability to connect inputs and objectives based on continuous monitoring of plant information. These systems will automatically adjust DCS parameters in real time by implementing bias and trim settings on pressures, temperatures, and flows that result in the optimal boiler performance for the parameter(s) being controlled. Combustion optimization programs are meant to act as a real-time boiler tuning mechanism, rather than an annual on-site manual tuning. Depending on the complexity of the system to which it is applied and on the quality of DCS installed at a facility, the improvement in boiler efficiency can be significant.

Based on the improvements to NO_x emissions that are often realized with completion of boiler combustion tuning, NO_x emissions may be achievable on a long-term annual average basis with a neural network system for constant online combustion optimization. Unlike the Riley Boilers, the Superheaters fire only two fuels. This limits the amount of burner and injector elevations as well as input parameters that need to be tuned. Furthermore, the Superheaters are only required to generate one steam source, which also reduces the amount of manual steam balancing required by operators. However, as discussed previously, combustion optimizer OEMs typically do not provide a guaranteed emissions reduction. Based on an analysis of the nominal NO_x emission reductions that were achieved between Superheater combustion tuning periods, the facility may be able achieve an additional 5% NO_x reduction on a long-term basis from the current annual average. However, further detailed review with the Superheater OEM as well as neural network OEMs would be required prior to determining actual emission reduction that could be achieved under various operating conditions. As such, combustion optimization is considered a technically feasible control option for the Superheaters. It is expected that the on-line combustion optimization could achieve 5% NO_x reduction resulting in a long-term average NO_x emission rate of 42 lb/hr.

6.2.2.2 Selective Non-Catalytic Reduction

As discussed in Section 5.2.2.3, SNCR is a viable technology for steam generators that combust liquid or gaseous fuels. The GPSP Superheaters have the potential to install reagent injectors in the furnace area; however, the temperature profile is unknown. Furnace temperature mapping and injection testing has not been modeled or studied in depth on the Superheaters. However, it is expected that the limiting process consideration may be the Superheater exhaust temperature. Plant personnel report that the temperature between the Superheater outlet and ID fan inlet is on average 620°F, which is within the ammonia salt formation temperature range for the sulfur levels present when high levels of tar oil are fired. At these exit temperatures, excess ammonia in the presence of sulfur will result in ammonium salt formation. ABS formation is expected to cause fouling within and downstream of the reheat duct and may impact the rear tube bundles, especially at low unit heat input or when one Superheater is offline for maintenance.

The formation of ammonium salts is a problem experienced by plants with high ammonia slip, high sulfur levels, and reduced temperature windows near the air preheaters. The unique operational configuration and fuels fired at the gasification facility exacerbates these sulfate salt formation issues by introducing unpredictable variations in sulfur content to the Superheaters over time. During periods of time when the facility is required to purge additional tar oil, it is expected that significant amounts of sulfur would be present in the Superheater flue gas and cause issues with ammonia salt formation if urea or ammonia is used for NO_x control. This can lead to significant ABS formation on heat transfer surface areas and lead to boiler malfunction, similar to that experienced by the Riley Boilers during SNCR testing. Furthermore, the baseline NO_x concentration (equivalent to 0.17 lb/MMBtu) is close to the emission rate achievable by SNCR systems. Due to historical issues with ammonia injection and the relatively low temperatures in the reheat duct, the SNCR technology option is not considered a technically feasible control option and will not be evaluated further.

6.2.2.3 Selective Catalytic Reduction

The SCR configuration that is most applicable to the Superheaters is the in-duct installation. Similar to SCR systems at combined cycle plants, the catalyst layers and ammonia injection grid would be installed downstream of the burners within the ductwork. This configuration, however, has numerous technical issues. Plant personnel have reported that the temperature between the Superheater outlet and ID fan inlet is on average 620°F. At these temperatures, there is the potential for ABS formation within the in-duct catalyst pores, limiting the NO_x removal

efficiency. ABS formation is even more concerning during time periods of high SO₂ formation from tar oil firing. Additionally, SO₂ in flue gas will oxidize to SO₃ as it passes over the SCR catalyst, likely increasing plant-wide sulfuric acid emissions. Due to the lack of downstream particulate collection devices on the gas- and liquid-fired steam generators, dry sorbent injection prior to the catalyst is not an option.

However, the critical issue with installation of an SCR downstream of the Superheaters is the presence of vapor phase alkali metals. As discussed in Section 5.2.2.3, combustion of the liquid fuels at GPSP is expected to have a detrimental effect on the SCR catalyst due to the expected presence of alkalis in the liquid fuels (e.g., tar oil). Since there is no treatment of the Superheater gas stream to remove these alkalis prior to the catalyst, SCR is determined to be technically infeasible for the Superheaters and will not be evaluated further.

6.2.2.4 NO_x Control Summary

Table 6-3 summarizes the results of the feasibility evaluation of available control options for GPSP.

Table 6-3. Summary of Technically Feasible NO_x Control Options – Superheaters

NO _x Control Option	Technically Feasible (Yes/No)	Technical Feasibility Summary
Combustion Optimization	Yes	Combustion optimization is considered a technically feasible control option for the GPSP Superheaters.
Selective Non-Catalytic Reduction (SNCR)	No	SNCR is not considered a technically feasible option for the Superheaters due to low reheat duct temperatures and presence of sulfur, which will lead to significant ABS formation issues within the existing ductwork and rear steam tube banks.
Selective Catalytic Reduction (SCR)	No	SCR applied to the Superheaters would introduce alkalis to the catalyst. As such, SCR is considered technically infeasible.

6.2.3 Effectiveness of NO_x Control Options

The NO_x control technologies that will be evaluated as part of the Four Factor Analysis are listed in Table 6-3 in descending order of control efficiency. Table 6-3 also provides control option-specific NO_x emission rates in terms of lb/hr. Emission rates shown in Table 6-3 represent average emission rates that the control options would be expected to achieve during normal operations on a long-term annual basis.

Table 6-4. Effectiveness of NO_x Control Options – Superheaters

Control Technology	NO_x Emission Rate ^(Note 1) lb/hr	% Reduction from Baseline Emission Rate
Combustion Optimization	42	5%
Baseline (Combustion Optimization / FGR / LNB)	44	--

Note 1. Emission rates shown represent average emission rates that the control options would be expected to achieve on an ongoing long-term basis under normal operating conditions for GPSP Superheaters. Emission rates are provided for comparative purposes, and should not be construed to represent proposed emission limits. Corresponding permit limits must be evaluated on a source-specific and control system-specific basis.

7. PACKAGE BOILER CONTROL MEASURES

The Package Boiler was permitted in 2014 during the Urea Project addition at GPSP. The Package Boiler subsequently commenced operation in December 2017. To minimize NO_x emissions from the Package Boiler, it was determined that ULNB would be used to achieve emission rates below the new source performance standard (NSPS). While a BACT analysis was not completed for NO_x control on the Package Boiler, an evaluation of the RBLC conclude that LNB is typically considered BACT for gas boilers of similar size. The Package Boiler is currently achieving a long-term average NO_x rate equivalent to approximately 30 ppmvd, which is comparable to other facilities operating with LNB or ULNB. As such, no additional NO_x emissions controls will be evaluated for the Package Boiler. Furthermore, the design of the Package Boiler is such that it can only fire natural gas or SNG. Based on SNG fuel analyses completed by GPSP, the sulfur content is considered non-detect. Therefore, no additional SO₂ emission controls will be evaluated for the Package Boiler at GPSP.

8. FLARE CONTROL MEASURES

The Main Flare is the primary control device for volatile process gases throughout the process areas in the facility. Process relief streams are either discharged through safety and control valves or equipment vents. One of the components of the process gases flared is hydrogen sulfide (H_2S). It is conservatively assumed that 100% of the H_2S vented to the flare from the process is combusted to SO_2 . The Startup Flare is used during startup, shutdown, and malfunction of the facility gasifiers. During startup, the gases originating from the lignite coal are not yet of sufficient composition for further processing and are instead flared.

S&L approached various flare vendors to gather feasible options for mitigating NO_x and SO_2 (H_2S) emissions from the flared process gases. S&L provided background information on a range of flare stream compositions, maximum volumetric and mass flows, typical emission concentration values, steam injection mass flows and pressures, flare tip diameters, general arrangement drawings, and brief operations and control descriptions. S&L requested feasible control technologies that could be implemented to reduce emissions from the baseline values provided in Table 4-1.

Under typical operation, H_2S is being scrubbed from the raw gas produced from the lignite gasification process via the Rectisol unit. Depending on which segment needs to be flared during upset conditions, certain flared components would not have substantial H_2S to remove. Most process streams are vented to the Main Flare during times of emergency pressure release, or during times of process failure in the gasification process. However, the Main Flare does experience a relatively consistent stream of process “leakage” from various locations within the facility. This leakage contributes approximately 35 lb/hr of SO_2 , which is significantly below the Riley Boiler WFGD outlet rates. The Startup flare is typically not flaring process gas (i.e., lock gas); instead, the majority of the flared fuel is SNG, which has non-detectable sulfur concentration. Overall, the baseline lb/hr SO_2 emissions from the Main and Startup Flares combined only comprise approximately 11% of the total plant baseline SO_2 emissions.

Recent technologies have emerged on the market for H_2S and volatile organic carbon (VOC) scrubbing instead of flaring to reduce emissions. However, these systems are typically applied to flare gases with very high H_2S concentrations. At GPSP, the process leakage gas going to the Main Flare has a typical H_2S concentration in the 0.05% range, which is well below the typical application of the emerging technology’s typical application, which

often deals with 5-20% ranges. Furthermore, these systems are designed for continuous operation at steady flow rates, rather than fluctuating purge conditions.

If an H₂S scrubbing system was pursued, the system would be best applied to treat the relatively continuous process leakage stream. There would be design issues to the system if treatment is expected of all other process stream purges sent to the Main Flare for process pressure relief in times of plant-wide upsets. Due to the safety concerns associated with adding back pressure to a pressure relief or emergency condition, it is suggested that other process gases would need to bypass the scrubber directly.

Prior to implementing the Riley Boiler WFGD system, the GPSP facility treated the gasification products and fuels using various H₂S scrubbing solutions, including Stretford® and Sulfolin®. The gaseous fuels were treated prior to combustion in the Riley Boilers; however, the facility was never able to continuously achieve the permitted limits in place at the time. During the years when the solutions were used for scrubbing, the effectiveness of the scrubbing was minimal; furthermore, the facility reported significant fugitive odors. It was concluded that the H₂S scrubbing was ineffective due to chemistry issues stemming from the fuel composition, specifically the various other sulfurous compounds that can be present in the products or purged gases. It is expected that there would be similar issues with the effectiveness of H₂S scrubbing of the flared gases.

Due to the limited experience with the flare scrubbing technology and low H₂S inlet rates, pilot testing would have to be completed to determine the continuous effectiveness of treating the process gas without impacts to the typical emergency operation of the flare. Additionally, because of the historic issues associated with H₂S scrubbing at GPSP, H₂S control is not considered a technically feasible technology at this time for SO₂ emission reduction on either the Main Flare or Startup Flare.

Additionally, no vendors were able to provide viable solutions for NO_x mitigation on the GPSP Main Flare or Startup Flare. Vendors cited numerous issues with providing solutions to this facility. One notable reason for not being able to provide additional controls was the already low baseline NO_x value (equivalent to approximately 0.06 lb/MMBtu). The vendors concluded it would be difficult to obtain significant reductions beyond what is already being achieved at the facility. For comparison purposes, SCR systems achieve 0.06 lb/MMBtu and these systems are considered BACT on coal-fired units.

For these reasons, there are no technically feasible control options available to further reduce SO₂ or NO_x emission from the Main or Startup Flares.

9. COSTS OF COMPLIANCE (STATUTORY FACTOR ONE)

The economic analysis performed as part of the Four Factor Analysis examines the cost-effectiveness of each control technologies identified in Table 5-3 and Table 6-4, on a dollar per ton of pollutant removed basis. Annual emissions, calculated for a particular control device, are subtracted from baseline annual emissions to calculate tons of pollutant controlled per year. For units with existing controls, the base case represents existing baseline actual emissions. Annual costs for each control option are calculated relative to the base case by adding annual operation and maintenance (O&M) costs to the annualized cost of capital and, if applicable, lost revenue due to extended outage required for installation of control equipment. Capital costs and lost revenues were annualized using a capital recovery factor based on an annual interest rate of 5.5% and equipment life of 20 years.^{27,28} Cost effectiveness (\$/ton) of a particular control option is simply the annual cost (\$/yr) divided by the annual reduction in annual emissions (ton/yr). In addition to cost-effectiveness relative to the base case, the incremental cost-effectiveness to go from one level of control to the next, more stringent, level of control may also be calculated to evaluate the incremental cost effectiveness of the more stringent control.

Capital and O&M cost estimates were developed for each of the evaluated control options. The GPSP cost estimates are conceptual in nature; thus, S&L did not procure equipment quotes specifically for the GPSP control system upgrades. Rather, equipment costs are based on conceptual designs developed for the retrofit control systems, preliminary equipment sizing developed for the major pieces of equipment (based on GPSP-specific design parameters, including typical fuels firing profiles, fuel characteristics, and flue gas temperatures and flow rates), and recent pricing for similar equipment. S&L would characterize the cost estimates for the GPSP retrofit technologies as “concept screening” cost estimates generally based on parametric models, judgment, or analogy.

Control technology equipment costs for the retrofit options were developed by scaling cost estimates prepared by S&L for other similar projects. Major equipment costs were developed based on equipment costs recently developed for similar projects, and include the equipment, material, labor, and all other direct costs needed to

²⁷ The assumed 20-year equipment life is consistent with the control system equipment life used by NDDH in its evaluation of NO_x and SO₂ control technologies for BART-eligible sources. (see, e.g., ND Regional Haze Final SIP, Appendix C.1, “BART Determination Study for Leland Olds Station Units 1 & 2, Basin Electric Power Cooperative, August 2006, pgs. 64 (NO_x controls) and 158 (SO₂ controls). See also, ND Regional Haze Final SIP, Appendix C4, “NO_x Best Available Control Technology Study for Milton R. Young Station Unit 1, Minnkota Power Cooperative, Inc., October 2006, pg. 3-22).

²⁸ Based on discussion with the NDDH, the state has elected to utilize the current Federal Reserve interest rate, which was 5.5% at the time of this analysis.

retrofit the units with the control technology. Sub-accounts for the capital cost estimates (e.g., mobilization and demobilization, consumables, contractor general and administration (G&A) expense, freight on materials, etc.) were developed by applying ratios from detailed cost estimates that were prepared for projects with similar scopes.

Additional costs were developed based on outage duration needed to tie-in the new control technology. Based on the location of the control technology (specifically the SCR), a special outage would be required to integrate into the flue gas path at a time when no process steam is required (i.e., when all three Riley Boilers and two Superheaters are offline). Since GPSP facility does not typically take a full facility outage on a yearly basis, a special outage is included; loss of facility profit is estimated for the outage and annualized similarly to the capital costs.

Fixed O&M costs include operating labor, maintenance labor, maintenance material, and administrative labor. Variable O&M costs include the cost of consumables, including reagent, water consumption, and electrical power requirements. Electrical power requirements reflect the additional power requirements associated with the operation of the new control technology (compared to the existing technology). All O&M costs reflect the incremental increase in O&M costs compared to the costs incurred to operate the existing control systems.

In addition to the cost effectiveness relative to the base case, the incremental cost-effectiveness to go from one level of control to the next more stringent level of control will also be calculated to evaluate the cost effectiveness of the more stringent control.

The results of the SO₂ and NO_x control cost evaluations are included below in Sections 9.1 and Section 9.2.

9.1 ECONOMIC EVALUATION – SO₂ CONTROLS

In the previous sections, it was determined that WFGD was established as BACT by the NDDH for the three Riley Boilers and continues to operate at approximately 97% reduction; thus no further SO₂ control options will be evaluated on the Riley Boilers. The two Superheaters currently generate an insignificant amount of SO₂ in comparison to the total SO₂ present at the stack. Furthermore, the WFGD is providing 96% overall SO₂ reduction for the combination of Superheaters and Riley Boilers, which is still within BACT levels. As such, no additional SO₂ control options are evaluated for the Superheaters.

The Package Boiler was recently commissioned and is only permitted to fire natural gas or SNG to limit SO₂ emissions. Samples taken by GPSP personnel confirm the sulfur composition of the SNG is non-detectable. Therefore, no additional SO₂ control options are evaluated for the Package Boiler.

Finally, there have been previous issues at GPSP with H₂S scrubbing along with limited experience with operating H₂S scrubbing devices on flares, especially with low H₂S concentrations and those which do not operate at steady flow rates. Because of this and the safety concerns with operating backend equipment on pressure relief flare systems, no SO₂ control options will be evaluated for the Main Flare and Startup Flare.

9.2 ECONOMIC EVALUATION – NO_x CONTROLS

Based on the technical feasibility analysis completed as part of the first factor, it was determined that NO_x control reduction is only feasible on the Riley Boilers and Superheaters. Table 9-1 presents the capital costs and annual operating costs associated with building and operating each control system for the three combined Riley Boilers or two combined Superheaters; annual emissions and pricing is not provided on an individual unit basis. Table 9-2 shows the average annual cost effectiveness for each control system. Additional cost details are provided in Appendix C.

Table 9-1. NO_x Control Cost Summary (\$2018)

Unit ^(Note 1)	NO _x Control Option	Total Capital Investment \$	Annual Capital Cost \$/yr	Annualized Outage Cost \$/yr	Annual Operating Cost \$/yr	Total Annual Cost \$/yr
Riley Boilers	TE-SCR	\$178,542,000	\$14,940,000	\$3,515,000	\$51,399,000	\$69,854,000
Superheaters	Combustion Optimization	\$1,7326,000	\$144,000	\$0	\$85,000	\$229,000

Note 1. Costs are provided for the combination of the three Riley Boilers or two Superheaters.

Table 9-2. NO_x Emissions Control System Cost Effectiveness (\$2018)

Unit <small>(Note 1)</small>	NO_x Control Option	Total Annual Cost \$/yr	Expected Emission Reduction tons NO _x /yr	Average Annual Cost Effectiveness <small>(Note 2)</small> \$/ton NO _x removed
Riley Boilers	TE-SCR	\$69,854,000	1,808	\$38,639
Superheaters	Combustion Optimization	\$229,000	10	\$23,596

Note 1. Costs are provided for the combination of the three Riley Boilers or two Superheaters.

Note 2. Average cost effectiveness for each control option is the total annual cost divided by the expected emission reduction.

The costs indicate that the average annual cost effectiveness of the NO_x control options for the facility range from \$23,596 per ton (Combustion Optimization on Superheaters) to \$38,639 per ton (TE-SCR) NO_x removed.

The Combustion Optimization option is expected to achieve 5% NO_x reduction from long-term average baseline levels without impact to Superheater performance. This option can be implemented on both Superheaters with additional capital and minor operating costs for a total cost effectiveness is \$23,596 per ton.

TE-SCR system costs have been included to remain consistent with the approach during the initial planning period (i.e., assuming technical feasibility and evaluating the control system for costs and cost effectiveness). Based on preliminary cost estimates, the cost effectiveness of a TE-SCR system is \$38,639 per ton to treat the NO_x from the three Riley Boilers.

10. TIME NECESSARY FOR COMPLIANCE (STATUTORY FACTOR TWO)

The time necessary for compliance is generally defined as the time needed for full implementation of the evaluated control options identified in Table 5-3 and Table 6-4. This includes the time needed to develop and implement the regulations, as well as the time needed to install the selected control equipment. The time needed to install the control equipment includes time for equipment procurement, design, fabrication, and installation. Therefore, compliance deadlines must consider the time necessary for compliance by setting a compliance deadline that provides a reasonable amount of time for the source to implement the control measure.

Table 10-1 includes estimated timeframes needed to implement each of the control technologies. Notably, the estimated timeframes do not account for time needed for North Dakota to develop and implement the regulations; nor the amount of time needed for EPA to take proposed and final action to approve North Dakota's SIP.

Table 10-1. NO_x Emissions Control System Implementation Schedule

NO _x Control Option	Design / Specification / Procurement (months)	Detail Design / Fabrication (months)	Construction / Commissioning / Startup (months)	Total (months after SIP approval)
TE-SCR on Riley Boilers	10	18	24	Up to 60 months
Combustion Optimization on Superheaters	2	4	4	Up to 60 months

11. ENERGY AND NON-AIR QUALITY ENVIRONMENTAL IMPACTS (STATUTORY FACTOR THREE)

The primary purpose of the environmental impact analysis is to assess collateral environmental impacts due to control of the regulated pollutant in question. Environmental impacts may include solid or hazardous waste generation, discharges of polluted water from a control device, visibility impacts, increased emissions of other criteria or non-criteria pollutants, increased water consumption, and land use impacts from waste disposal.

11.1 ENVIRONMENTAL IMPACTS

The Riley Boilers and Superheaters are currently equipped with a combination of LNB, FGR and OFA systems for NO_x control and wet ammonia scrubber technology for SO₂ control. The ammonia reagent used in the ammonia-based FGD system reacts with SO₂ in the flue gas to form ammonium sulfate and ammonium sulfite solids. The solids are either recycled to the system for reuse or removed from the system and sold as fertilizer or disposed as nonhazardous solid waste. The existing WFGD system also requires water to quench the flue gas. Based on the design of the control system, the WFGD uses approximately 640 gpm of makeup water for SO₂ control. Collateral environmental impacts associated with the existing control systems include water consumption and increased solid waste generation. There were no collateral impacts associated with the combustion optimization or LNB/OFA/FGR systems previously implemented.

Based on a review of potential non-air quality environmental impacts, there are potentially significant collateral environmental impacts identified for and the NO_x control options. The TE-SCR catalyst oxidizes some of the SO₂ to SO₃ in addition to catalyzing the reaction between NO_x and ammonia. There could be the potential for increased SO₃ emissions with the use of a TE-SCR. The SO₃ will react with the moisture in the stack to form sulfuric acid emissions and react with the ammonia slip to form ABS. If it is determined a dry sorbent injection system is required for the reduction of SO₃ emissions prior to the WFGD, the system will increase the solid waste generated and may affect sales of the ammonium sulfate fertilizer. If fertilizer cannot be sold, it will need to be disposed of in a solid waste landfill. There would be some ammonia slip emissions from a TE-SCR in the range of 2 ppm, and there is no means to capture the ammonia slip emissions from the TE-SCR since it would be installed downstream of the WFGD. Finally, the TE-SCR system would require combustion of SNG in a duct burner to heat the flue gas. This would result in additional NO_x, CO and VOC emissions.

Impacts from the incorporation of the combustion optimization system on the Superheaters are expected to be less significant than the TE-SCR. Based on tuning the combustion for minimizing NO_x formation, there would be expected increases in CO emissions, since they have an inverse relationship with respect to combustion.

11.2 ENERGY IMPACTS

The facility relies on production of steam in the Riley Boilers, Superheaters, and Package Boiler as the heat energy for other processes within the gasification facility. Options that include changes to the combustion temperature for NO_x control may result in sub-optimal steam production rates or quality. As such, if the combustion optimization systems may not be able to maintain the desired boiler efficiency while tuning operating conditions for minimizing NO_x production, additional fuel may have to be fired to maintain steam production rate and quality. As such, the measured efficiency of the boiler may decrease, and subsequently result in higher mass emission rates due to higher fuel throughput. The TE-SCR option would increase pressure drop through the control systems, and increase the electricity consumption of the facility.

Although several of the control options have energy impacts, none of the impacts are considered significant enough as to disqualify any of the options from consideration in the Four Factor Analysis. In order to account for potential energy impacts associated with each option, the electrical power cost associated with operating the control systems have been included as an annual operating cost in the economic impact assessment.

11.3 ENVIRONMENTAL / ENERGY IMPACTS SUMMARY

A summary of the Statutory Factor 3 environmental and energy impact analysis is provided in Table 11-1.

Table 11-1. Summary of Energy and Non-Air Quality Environmental Impacts

Control Option	Collateral Environmental & Energy Impacts
Baseline	<ul style="list-style-type: none"> ➤ GPSP Riley Boilers are currently equipped with WFGD / WESP control systems for SO₂ control. The Riley Boilers and Superheaters are equipped with a combination of LNB, FGR, and OFA for NO_x control. Existing collateral environmental and energy impacts include: ➤ Solid WFGD by-product management or disposal ➤ Increased water consumption ➤ Increased electrical power requirements
<u>NO_x Control Options</u>	
Selective Catalytic Reduction (SCR) - Tail End Configuration (Riley Boilers)	<ul style="list-style-type: none"> ➤ Increased electrical power requirements ➤ Increased ammonia slip emissions and potential for ABS emissions ➤ Potential increase in SO₃ emissions ➤ Additional solid waste disposal ➤ Additional NO_x, CO, and VOC emissions from duct firing
Combustion Optimization (Superheaters)	<ul style="list-style-type: none"> ➤ Potential decrease in boiler efficiency to reduce NO_x emissions ➤ Potential increase in CO emissions

12. REMAINING USEFUL LIFE (STATUTORY FACTOR FOUR)

The evaluation of NO_x and SO₂ controls options should consider the source's "remaining useful life" in determining the costs of compliance. The remaining useful life is the difference between the date that controls would be put in place and the date that the facility permanently ceases operation. If the remaining useful life of the unit is shorter than the useful life of a particular control option, the remaining useful life should be used for annualizing costs. If the remaining useful life exceeds the useful life of the control options, the remaining useful life has no effect on the cost evaluation.

Under the current GPSP resource plan, the remaining useful life of the facility is expected to be greater than 20 years. Therefore, the remaining useful life has no impact on the annualized cost of control under the current regulatory framework. However, the implementation of additional controls has the potential to reduce the facility's minimal profit margin, which may adversely impact the facility's planned remaining life. In the event that occurs, GPSP would request an opportunity to reevaluate economic impacts and the facility's remaining useful life.

13. FOUR-FACTOR ANALYSIS SUMMARY

At the request of NDDH, a Four Factor Analysis was prepared for GPSP. The analysis identified SO₂ and NO_x control options for the three Riley Boilers, two Superheaters, auxiliary Package Boiler, Main Flare, and Startup Flare, and evaluated each of the control measures for the following four statutory factors:

1. The estimated cost of compliance;
2. The time necessary for compliance;
3. The energy and non-air quality environmental impacts of compliance; and
4. The remaining useful life of any potentially affected anthropogenic source of visibility impairment.

The technical feasibility evaluation concluded that there are no technically feasible options for further SO₂ control on the individual sources. The evaluation prepared for NO_x controls options indicates that the average annual cost effectiveness for the facility ranges from \$23,596 per ton (Combustion Optimization on Superheaters) to \$38,639 per ton (TE-SCR on Riley Boilers) NO_x removed.

The time necessary for compliance for the NO_x control options, the time necessary for compliance ranges from 10 months (combustion optimization) to 52 months (TE-SCR); however, GPSP would expect that the state would allow up to 60 months to achieve compliance to be consistent with the first planning period.

An evaluation of energy impacts indicates that certain control options (e.g., TE-SCR) will increase electrical power requirements due to increased pressure drop. Use of a combustion optimization system for NO_x control may also result in reduced boiler efficiency which would increase the amount of fuels fired to maintain steam generation. Collateral environmental impacts with regard to TE-SCR include an increase in solid waste generation due to sorbent injection; increases in other stack emission such as CO, VOC and ammonia slip; as well as additional power consumption.

Regarding remaining useful life, the GPSP owners do not have an enforceable or suggested remaining useful life that is less than 20 years. However, implementation of control technologies that eliminate any profitability for the facility may have an effect on the remaining life. Nevertheless, a 20 year remaining useful life is evaluated.

APPENDIX A

NORTH DAKOTA DEPARTMENT OF HEALTH LETTER

May 18, 2018

Mr. Daniel Whitley
Dakota Gasification Company
420 County Road 26
Beulah, ND 58523

Re: Regional Haze
Second Planning Period

Dear Mr. Whitley:

The Department of Health (Department) has begun work on the second planning period (Round 2) State Implementation Plan (SIP) for regional haze. In Round 1 of the regional planning process, the emphasis was on Best Available Retrofit Technology (BART) and making reasonable progress towards the national visibility goal. In Round 2, there are no BART requirements; therefore, we will focus on making reasonable progress. The reasonable progress analysis will be made using the four factors in Section 169A(g)(1) of the Clean Air Act:

The four factors are:

1. The cost of compliance
2. The time necessary to achieve compliance
3. The energy and non-air quality environmental impact of compliance; and
4. The remaining useful life of any existing source subject to such requirements

Guidance provided by the U.S. Environmental Protection Agency (Draft Guidance on Progress Tracking Metrics, Long Term Strategies, Reasonable Progress Goals and Other Requirements for Regional Haze State Implementation Plans for the Second Implementation Period at https://www.epa.gov/sites/production/files/2016-07/documents/draft_regional_haze_guidance_july_2016.pdf) indicates the Department must address 80% of the visibility impairment caused by in-state sources. Data from the IMPROVE monitoring sites at Theodore Roosevelt National Park (TRNP) and Lostwood Wilderness Area (LWA) indicate that sulfates and nitrates continue to be the largest contributors to visibility impairment in these areas. The primary precursors of sulfates and nitrates are emissions of sulfur dioxide (SO₂) and nitrogen oxides (NO_x).

The Great Plains Synfuels Plant has been identified as a significant source of SO₂ and NO_x emissions. Therefore, the Department requests that you prepare a "four factors" analysis for your facility. The analysis should be prepared using the draft EPA guidance noted above. The analysis should include all source units that emit through the main stack as well as the flares at the facility.

Preparation of the Round 2 Regional Haze SIP will require extensive planning and review of emission sources in North Dakota. The Department will be working with the Western Regional Air Partnership (WRAP) to prepare the Round 2 SIP. WRAP will be conducting air quality modeling of potential regional emissions reductions in early 2019. The Department asks that your "four factors" analysis be submitted by January 31, 2019.

If you have any questions, please contact David Stroh of my staff at (701)328-5188.

Sincerely,

Terry L. O'Clair
Director
Division of Air Quality

Appendix C – Supporting Modeling Data

C.1 – Normalization of Regional, State/Sector Source Apportionment Results

The purpose of this document is to outline a method which was used to normalize the 2028 CAMx model source apportionment results to the overall 2028 visibility projections for each Federal Class I Area. When normalized, the sum of all regional and state/sector apportionment model outputs will correspond to the overall 2028 visibility projections when reviewing the species-specific or total light extinction. *Currently, the regional (high-level) and the state/sector (low-level) model apportionment results are determined solely from the CAMx model output. Meaning, they will not correlate to the 2028 visibility projections until they are normalized.*

Annual average data is used in this document to provide a reasonable representation of the normalized regional, state, and/or sector specific contributions to light extinction in 2028.

Three steps were taken to perform this normalization.

Step 1

Determine species specific normalization factors. Take the 2028 visibility projection (2028 OTBa2EPA) for each species and divide by the 2028 CAMx source contribution model results (2028OTBa2).

The 2028 CAMx model results are found at the TSSv2 model product 1, indicated by the red box in Figure 1:

Figure 1: 2014 IMPROVE data, 2014 Model Results, RepBase Model Results, and 2028 Source Contribution Model Results

The 2028 Visibility projections are found at the TSSv2 Model Product 3, indicated by the red box in Figure 2:

Figure 2: 2014-2018 IMPROVE data and 2028 Visibility Projections Using Different Scenarios

Table 1 shows the species-specific normalization factors for Theodore Roosevelt National Park on the most impaired days.

Table 1: 2028 Model Results, 2028 Visibility Projections, and Normalization Factors

	AmmNO3	AmmSO4	CM	EC	OMC	Sea Salt	Soil	Total	Notes
2028OTBa2 EPA	10.56	13.34	2.11	0.80	2.40	0.16	0.26	29.6	Model Product 3
Model 2028OTBa2	3.40	8.14	0.59	0.58	2.36	0.05	0.20	15.3	Model Product 1
Normalization Factor	3.11	1.64	3.58	1.38	1.02	2.88	1.27	-	MP3 ÷ MP1

AmmSO4 example: $13.34/8.14 = 1.64$

Step 2

Use normalization factors to calculate regional contributions to the 2028 visibility Projection.

The annual regional source apportionment results can be found in TSSv2 model products 10, 11, and/or 12. Model Product 11 is displayed in Figure 3. The sum of all data in the Figure 3 equals the total modeled light extinction for 2028 (15.3 Mm^{-1}) from Table 1 at the end of Step 1.

Figure 3:2028 Model Results of Regional Contribution to Light Extinction

15.3 Mm^{-1} can be normalized to the 2028 visibility projection (29.6 Mm^{-1} in Table 1) by applying each species normalization factor, shown in Table 2. Total AmmNO3 example: $3.43 \times 3.11 = 10.67$. US_Anthro AmmSO4 example: $2.21 \times 1.64 = 3.63$.

Table 2: 2028 Regional Apportionment Model Results, Species Multiplication Factors, and Normalized Regional Apportionment

Source Category	AmmNO3	AmmSO4	CM	EC	OMC	Sea Salt	Soil	Total
US_Anthro	1.42	2.21	0.35	0.29	1.15	0.00	0.15	5.58
Int_Anthro	1.45	4.30	0.14	0.24	0.34	0.00	0.06	6.53
Natural	0.52	1.51	0.11	0.02	0.61	0.06	0.00	2.82
US_RxWildlandFire	0.02	0.04	0.00	0.02	0.12	0.00	0.00	0.20

CanMexFire	0.00	0.01	0.00	0.01	0.02	0.00	0.00	0.05
Total	3.43	8.10	0.60	0.59	2.32	0.06	0.21	15.32

Multiplied by

Site	AmmNO3	AmmSO4	CM	EC	OMC	Sea Salt	Soil
THRO1	3.11	1.64	3.58	1.38	1.02	2.88	1.27

Equals the normalized regional apportionment results

Source Category	AmmNO3	AmmSO4	CM	EC	OMC	Sea Salt	Soil	Total
US_Anthro	4.43	3.63	1.26	0.39	1.18	0.00	0.19	11.07
Int_Anthro	4.51	7.05	0.49	0.33	0.35	0.00	0.07	12.81

Source Category	AmmNO3	AmmSO4	CM	EC	OMC	Sea Salt	Soil	Total
Natural	1.61	2.47	0.40	0.03	0.62	0.16	0.00	5.29
US_RxWildlandFire	0.05	0.07	0.01	0.02	0.12	0.00	0.00	0.28
US_WildFire	0.07	0.03	0.00	0.02	0.07	0.00	0.00	0.20
CanMexFire	0.00	0.02	0.00	0.01	0.02	0.00	0.00	0.07
Total	10.67	13.28	2.16	0.82	2.36	0.16	0.26	29.72

The normalized regional apportionment results are shown in Figure 4. The sum of all data in the figure below equals the 29.7 Mm^{-1} (consistent with the above normalized data).

Figure 4: Source Contributions to Light Extinction Normalized to the 2028 Visibility Projection

This source contribution data now corresponds to the 2028 visibility projection. Confirmed by review of TSSv2 model product 4 when looking at the total light extinction projected for 2028. See the red box in Figure 5. The total light extinction projection for Theodore Roosevelt NP is 40.6 Mm^{-1} which consists of 29.72 Mm^{-1} of species extinction and approximately 11 Mm^{-1} of Rayleigh scattering.

Figure 5: Total Light Extinction Projection for 2028, Including Rayleigh

Therefore, 40.6 Mm^{-1} (total light extinction) minus approximately 11 Mm^{-1} (Rayleigh) equals 29.7 Mm^{-1} , consistent with the normalized regional data displayed in Figure 4 and listed in Table 2. With the normalized data, the information can now be discussed in both absolute and relative terms. In other words, for Theodore Roosevelt National Park, it can be said that 40.6 Mm^{-1} is the projected light extinction for 2028. Of the 40.6 Mm^{-1} , 11.1 Mm^{-1} (27%) are from US_Anthro emissions. Of the 11.1 Mm^{-1} from US_Anthro, 3.6 Mm^{-1} (9% overall) are from US_Anthro AmmSO₄. In different context, of the 40.6 Mm^{-1} , 13.3 Mm^{-1} (33%) are from AmmSO₄. Of the 13.3 Mm^{-1} from AmmSO₄, 3.6 Mm^{-1} (9% overall) are from US_Anthro emissions.

Step 3

Use AmmNO₃ normalization factors to calculate state/sector contributions to the 2028 light extinction. State/sector contributions to light extinction were only determined for AmmNO₃ and AmmSO₄. (*Repeat this process for AmmSO₄*)

The AmmNO₃ annual state/sector source apportionment results can be found in TSSv2 model product 9. Model Product 9 is shown in Figure 6 for AmmNO₃. The sum of all data in Figure 6 equals the 1.37 Mm⁻¹.

Figure 6: State and Sector Breakdown of AmmNO₃ Light Extinction, US Anthropogenic Sources Only

1.37 Mm⁻¹ can be normalized to 4.3 Mm⁻¹ by applying the AmmNO₃ normalization factor to each of the state/sector values from Figure 6. This normalization is displayed in Table 3:

Table 3: 2028 State/Sector Apportionment Model Results, AmmNO₃ Multiplication Factor, and Normalized State/Sector Apportionment

Grand Total	0.37	2.31	1.18	0.26	0.15	4.26

The normalized state/sector AmmNO₃ apportionment result is displayed in Figure 7. The sum of all data in the Figure 7 equals the 4.3 Mm⁻¹. 4.3 Mm⁻¹ is slightly lower than the 4.4 Mm⁻¹ listed in Table 2. The difference results from the exclusion of US Anthropogenic boundary conditions impacts. These boundary condition impacts accounted for 0.054 Mm⁻¹ of the 2028 model results, an insignificant contribution.

Figure 7: State and Sector Contributions to Light Extinction Normalized to the 2028 Visibility Projection

This state/sector AmmNO₃ data now corresponds to the 2028 visibility projection for the US_Anthro component of light extinction. This is confirmed by review of normalized data displayed in Table 2.

The Normalized state/sector data can now be compared to TSSv2 model product 4, for both the total light extinction (Figure 5) and/or the AmmNO₃ light extinction projection for 2028. See the red box in Figure 8. 10.6 Mm⁻¹ is the total AmmNO₃ light extinction.

Figure 8: AmmNO3 Light Extinction Projection for 2028 (No Rayleigh)

The normalized state/sector results can now be discussed in absolute or relative terms. In other words, for Theodore Roosevelt National Park, 10.6 Mm^{-1} is the projected AmmNO3 light extinction for 2028, accounting for 26% of the total 2028 projected light extinction. Of the 10.6 Mm^{-1} , 4.3 Mm^{-1} (11% overall) are AmmNO3 from US_Anthro emissions (not including the US boundary conditions extinction, which is very small). Of the 4.3 Mm^{-1} of AmmNO3 light extinction from US_Anthro, 2 Mm^{-1} (5% overall) are from North Dakota Oil and Gas.

Conclusion

Table 4 provides all regional and the North Dakota sector percent contributions to light extinction. North Dakota's species light extinction contributions of coarse mass, elemental carbon, organic mass, sea salt and soil are included in the "Remaining US" row. The modeling was not performed for these species since they are of lesser concern due to small contributions to light extinction on the most impaired days.

Table 4: State Sector and Regional Percent Breakdown of Contributions to Light Extinction

The information from Table 4 is shown in Figure 9 as the vertical column. The gray dashed line is the unadjusted uniform rate of progress (glidepath). The black line is the adjusted glidepath. The orange line is the 5-year IMPROVE rolling average light extinction data. The blue line is the baseline light extinction from 2000–2004. The black diamond is the 2028 visibility projection. The column is the breakdown of the categories contributing to the 2028 visibility projection organized consistent with the legend from the top down.

Figure 9: Theodore Roosevelt NP Normalized Apportionment Data Plotted with the 2028 Visibility Projection and Uniform Rate of Progress (with and without adjustment for International and Prescribed Wildland Fires)

C.2 – Regional, State/Sector Source Apportionment Results

1 International and Natural Impacts on North Dakota Visibility

This section contains the data from the high-level source apportionment results from the modeling performed by WRAP.¹ WRAP completed modeling to separate out the impacts of emissions from US anthropogenic sources (US_Anthro), international sources (Int_Anthro), natural sources (Natural), prescribed wildland burning (US_RxWildlandFire), US wildfires (US_WildFire), and Canadian Mexican Wildfire (CanMexFire). This modeling indicates that contributions from international sources significantly impair the visibility in North Dakota Class I areas. US anthropogenic sources also contribute significantly to the visibility impairment and natural sources also have a sizable influence on visibility. The categories of US wildfire, Canadian Mexican wildfire, and prescribed wildland burning typically had little impact on visibility impairment for the most impaired and/or clearest days. When looking at all monitor days or the haziest days, emissions from extreme episodic events (e.g. wildfires) tend to dominate the visibility impairment when impairment is at its highest levels, discussed in Section 3.3 of the main SIP document.

The high-level source apportionment results are discussed in Section 1.1 for the most impaired days and Section 1.2 for the clearest days. The data is further separated by source category and aerosol species contributing to light extinction in the respective subsections.

The aerosol species which contribute to light extinction are ammonium nitrate, ammonium sulfate, organic mass, elemental carbon, coarse mass, soil, and sea salt. The aerosol species of most significance to North Dakota Class I areas are ammonium nitrate and ammonium sulfate.

The modeling was completed for the Representative Baseline (RepBase) and the 2028 inventory projection (2028OTB). For details on RepBase and 2028OTB emission inventories, see Sections 4.1.4 and 4.1.6 of the main SIP document, respectively. Since there are limited expected changes in emissions between the RepBase and 2028 OTB emissions, the model results displayed in in Section 1.1 and Section 1.2 are for the 2028OTB emissions scenario. For both the most impaired days and the clearest days, the US_Anthro light extinction was modeled to be lower in the 2028OTB scenario than the RepBase scenario. These results, however, were not significantly different. The RepBase light extinction projections are available on the WRAP TSSv2.²

North Dakota shares a border with the Canadian Provinces of Manitoba and Saskatchewan. These provinces, along with the provinces of Alberta and British Columbia, are upwind of the prevailing wind direction causing North Dakota to be impacted by the airshed. Emissions from Canadian coal fired EGUs along with oil and gas development are significant and contribute to visibility impairment in North Dakota Class I areas. Emissions from nearby Canadian EGUs are discussed in Section 4.7.1 and emissions

² Available at: <https://views.cira.colostate.edu/tssv2/Express/ModelingTools.aspx>. See model products 10, 11, and 12 for “Most Impaired Days” and “Clearest Days” for model scenario “RepBase”. (Last visited March 9, 2021)

from oil and gas operations are discussed in Section 4.7.2 of the main SIP document. Canadian anthropogenic impairment accounts for 66% of the total international impairment projected for LWA and 50% at TRNP. The remaining international impairment is from international anthropogenic contributions from outside the CAMx 36-km domain boundary as defined by the GEOS-Chem global model (international boundary condition impacts). 32% of LWAs international anthropogenic impairment and 50% of TRNPs is from contributions outside the 36-km modeling domain.³

1.1 Most Impaired Days

1.1.1 Source Category Light Extinction on the Most Impaired Days

Figure 1 and Figure 2 display the 2028OTB source apportionment results for the average of the most impaired days for aerosol species within the five major source categories. The five major source categories are: US_Anthro, Int_Anthro, Natural, US_RxWildlandFire, US_WildFire, and CanMexFire. Table 1 and Table 2 display the numerical data corresponding to Figure 1 and Figure 2 for LWA and TRNP, respectively.

Figure 1: LWA 2028OTB Light Extinction on the Most Impaired Days by Source Category

Figure 1 shows approximately equal light extinction from US_Anthro and Int_Anthro for the species of ammonium nitrate and ammonium sulfate on the most impaired days at LWA. The total light extinction from US_Anthro and Int_Anthro is also very similar at LWA, with organic mass making up the largest

³ A complete breakdown of the modeled regional source group contributions can be found at: <https://views.cira.colostate.edu/tssv2/Express/ModelingTools.aspx>. See model product 10 for “Most Impaired Days”.

difference in impairment on the most impaired days. Impacts from Natural are the next largest category but are considerably less than US_Anthro and Int_Anthro. US_RxWildlandFire, US_WildFire, and CanMexFire are insignificant for the MID at LWA.

Table 1: LWA 2028OTB Light Extinction on the Most Impaired Days by Source Category

Source Category	Ammonium Nitrate	Ammonium Sulfate	Coarse Mass	Elemental Carbon	Organic Mass	Sea Salt	Soil	Total	Percent of Total
US_Anthro	7.39	6.14	0.98	0.53	1.23	0.00	0.16	16.43	42%
Int_Anthro	7.42	6.72	0.55	0.75	0.43	0.00	0.08	15.96	40%
Natural	2.75	2.05	0.32	0.06	0.83	0.23	0.00	6.23	16%
US_RxWildlandFire	0.06	0.08	0.01	0.07	0.22	0.00	0.00	0.44	1%
US_WildFire	0.01	0.03	0.00	0.02	0.05	0.00	0.00	0.11	0%
CanMexFire	0.04	0.04	0.01	0.09	0.11	0.00	0.00	0.28	1%
Total	17.67	15.05	1.86	1.52	2.88	0.23	0.24	39.45	100%

A review and breakdown of Table 1 shows the following significant contributors to light extinction. The US_Anthro source category accounts for 42% of the total light extinction on the most impaired days at LWA. Much of the total light extinction from US_Anthro is comprised of ammonium nitrate and ammonium sulfate. US_Anthro ammonium nitrate and ammonium sulfate account for 19% and 16% of the total light extinction, respectively. Int_Anthro accounts for 40% of the total light extinction on the most impaired days at LWA. Like US_Anthro, much of the Int_Anthro total light extinction is from ammonium nitrate and ammonium sulfate. Int_Anthro ammonium nitrate and ammonium sulfate account for 19% and 17% of the total light extinction, respectively. The only significant remaining category of total light extinction is Natural at 16%. Much of the total light extinction from Natural is also comprised of ammonium nitrates at 7% and ammonium sulfates at 5%.

Figure 2: TRNP 2028OTB Light Extinction on the Most Impaired Days by Source Category

Figure 2 shows Int_Anthro ammonium sulfate light extinction is approximately two times the US_Anthro ammonium sulfate extinction on the most impaired days at TRNP. US_Anthro ammonium nitrate light extinction is approximately equal to Int_Anthro ammonium nitrate light extinction on the most impaired days. Combined, US_Anthro ammonium nitrate and ammonium sulfate light extinction is considerably less than the contribution from Int_Anthro. Higher contributions from organic mass and coarse mass from US_Anthro lessen the overall difference in impairment between US_Anthro and Int_Anthro. Impacts from Natural are the next largest category but are considerably less than US_Anthro and Int_Anthro. US_RxWildlandFire, US_WildFire, and CanMexFire are insignificant for the MID at TRNP.

Table 2: TRNP 2028OTB Light Extinction on the Most Impaired Days by Source Category

Source Category	Ammonium Nitrate	Ammonium Sulfate	Coarse Mass	Elemental Carbon	Organic Mass	Sea Salt	Soil	Total	Percent of Total
US_Anthro	4.43	3.63	1.26	0.39	1.18	0.00	0.19	11.07	37%
Int_Anthro	4.51	7.05	0.49	0.33	0.35	0.00	0.07	12.81	43%
Natural	1.61	2.47	0.40	0.03	0.62	0.16	0.00	5.29	18%
US_RxWildlandFire	0.05	0.07	0.01	0.02	0.12	0.00	0.00	0.28	1%
US_WildFire	0.07	0.03	0.00	0.02	0.07	0.00	0.00	0.20	1%
CanMexFire	0.00	0.02	0.00	0.01	0.02	0.00	0.00	0.07	0%
Total	10.67	13.28	2.16	0.82	2.36	0.16	0.26	29.72	100%

A review and breakdown of Table 2 shows the following significant contributors to light extinction. The US_Anthro source category accounts for 37% of the total light extinction on the most impaired days at TRNP. Much of the total light extinction from US_Anthro is comprised of ammonium nitrate and ammonium sulfate. US_Anthro ammonium nitrate and ammonium sulfate account for 15% and 12% of the total light extinction, respectively. Int_Anthro accounts for 43% of the total light extinction on the most impaired days at TRNP. Like US_Anthro, much of the Int_Anthro total light extinction is from ammonium nitrate and ammonium sulfate. Int_Anthro ammonium nitrate and ammonium sulfate account for 15% and 24% of the total light extinction, respectively. The only significant remaining category of total light extinction is Natural at 18%. Much of the total light extinction from Natural is also comprised of ammonium nitrates at 5% and ammonium sulfates at 8%.

1.1.2 Species Light Extinction on the Most Impaired Days

Figure 3 and Figure 4 display the 2028OTB source apportionment results for the average of the most impaired days for aerosol species within the five major source categories. The five major source categories are: US_Anthro, Int_Anthro, Natural, US_RxWildlandFire, US_WildFire, and CanMexFire. Table 3 and Table 4 display the numerical data corresponding to Figure 3 and Figure 4 for LWA and TRNP, respectively. The data in these figures and tables is the same as Section 1.1.1. The difference is how the data is displayed. The aerosol species are plotted along the x-axis and the light extinction contribution from the source category is separated by species.

Figure 3: LWA 2028OTB Light Extinction on the Most Impaired Days by Species

Figure 3 emphasizes a few important items for LWA on the most impaired days. The most significant aerosol species contributing to light extinction are ammonium nitrate and ammonium sulfate. Light extinction from US_Anthro and Int_Anthro are nearly equal. The remaining species of light extinction: organic mass, elemental carbon, coarse mass, sea salt, and soil, are minimal.

Table 3: LWA 2028OTB Light Extinction on the Most Impaired Days by Species

Source Category	US_Anthro	Int_Anthro	Natural	US_RxWild landFire	US_Wild Fire	CanMex Fire	Total	Percent of Total
Ammonium Sulfate	6.14	6.72	2.05	0.08	0.03	0.04	15.05	38%
Ammonium Nitrate	7.39	7.42	2.75	0.06	0.01	0.04	17.67	45%
Organic Mass	1.23	0.43	0.83	0.22	0.05	0.11	2.88	7%
Elemental Carbon	0.53	0.75	0.06	0.07	0.02	0.09	1.52	4%
Coarse Mass	0.98	0.55	0.32	0.01	0.00	0.01	1.86	5%
Sea Salt	0.00	0.00	0.23	0.00	0.00	0.00	0.23	1%
Soil	0.16	0.08	0.00	0.00	0.00	0.00	0.24	1%
Total	16.43	15.96	6.23	0.44	0.11	0.28	39.45	100%

The light extinction contribution by species from Table 3 shows ammonium sulfate and ammonium nitrate are the most significant. Ammonium sulfate accounts for 38% of the total light extinction on the most impaired days at LWA. 17% of the total light extinction is caused by ammonium sulfate from Int_Anthro, 16% is from US_Anthro, and 5% is from Natural. Ammonium nitrate accounts for 45% of the total light extinction. 19% of the total light extinction is caused by ammonium nitrate from Int_Anthro, 19% is from US_Anthro, and 7% is from Natural. The remaining noteworthy species causing light extinction is organic mass, which contributes only 7% to the total light extinction.

Figure 4: TRNP 2028OTB Light Extinction on the Most Impaired Days by Species

Figure 4 emphasizes a few important items for TRNP on the most impaired days. Light extinction from ammonium sulfate is the most significant aerosol species and Int_Anthro contributes the most to the overall light extinction. Int_Anthro ammonium sulfate light extinction is one and a half times larger than the next largest contributor to light extinction, which is ammonium nitrate from US_Anthro and Int_Anthro. US_Anthro and Int_Anthro light extinction from ammonium nitrate are nearly equal. The most significant remaining contributor to light extinction is US_Anthro ammonium sulfate. The remaining species of light extinction: organic mass, elemental carbon, coarse mass, sea salt, and soil, are much smaller in comparison to ammonium sulfate and ammonium nitrate.

Table 4: TRNP 2028OTB Light Extinction on the Most Impaired Days by Species

Source Category	US_Anthro	Int_Anthro	Natural	US_RxWild landFire	US_Wild Fire	CanMex Fire	Total	Percent of Total
Ammonium Sulfate	3.63	7.05	2.47	0.07	0.03	0.02	13.28	45%
Ammonium Nitrate	4.43	4.51	1.61	0.05	0.07	0.00	10.67	36%
Organic Mass	1.18	0.35	0.62	0.12	0.07	0.02	2.36	8%
Elemental Carbon	0.39	0.33	0.03	0.02	0.02	0.01	0.82	3%

Source Category	US_Anthro	Int_Anthro	Natural	US_RxWild landFire	US_Wild Fire	CanMex Fire	Total	Percent of Total
Coarse Mass	1.26	0.49	0.40	0.01	0.00	0.00	2.16	7%
Sea Salt	0.00	0.00	0.16	0.00	0.00	0.00	0.16	1%
Soil	0.19	0.07	0.00	0.00	0.00	0.00	0.26	1%
Total	11.07	12.81	5.29	0.28	0.20	0.07	29.72	100%

The light extinction contribution by species from Table 4 shows ammonium sulfate and ammonium nitrate are the most significant. Ammonium sulfate accounts for 45% of the total light extinction on the most impaired days at TRNP. 24% of the total light extinction is caused by ammonium sulfate from Int_Anthro, 12% is from US_Anthro, and 8% is from Natural. Ammonium nitrate accounts for 36% of the total light extinction. 15% of the total light extinction is caused by ammonium nitrate from Int_Anthro, 15% is from US_Anthro, and 5% is from Natural. The remaining noteworthy species causing light extinction is organic mass and coarse mass, which contribute 8% and 7% to the total light extinction, respectively.

1.1.3 Most Impaired Days Conclusion

In summary, the contributors to light extinction on the most impaired days for both LWA and TRNP come from four main areas: Int_Anthro ammonium sulfate, Int_Anthro ammonium nitrate, US_Anthro ammonium sulfate, and US_Anthro ammonium nitrate. Light extinction from Natural are smaller in comparison than US_Anthro and Int_Anthro at both LWA and TRNP, but still account for 16% and 18% of total light extinction, respectively.

The high-level source apportionment data presented in Sections 1.1.1 and 1.1.2 supports the Department's decision to use an adjusted glidepath for both LWA and TRNP to account for international anthropogenic emissions and wildland prescribed fires⁴.

1.2 Clearest Days

1.2.1 Source Category Light Extinction on the Clearest Days

Figure 5 and Figure 6 display the 2028OTB source apportionment results for the average of the clearest days for aerosol species within the five major source categories. The five major source categories are: US_Anthro, Int_Anthro, Natural, US_RxWildlandFire, US_WildFire, and CanMexFire. Table 5 and Table 6 display the numerical data corresponding to Figure 5 and Figure 6 for LWA and TRNP, respectively.

⁴ 40 CFR 51.308(f)(1)(vi)(B)

Figure 5: LWA 2028OTB Light Extinction on the Clearest Days by Source Category

Figure 5 shows significantly greater light extinction from Int_Anthro for the species of ammonium nitrate and ammonium sulfate on the Clearest days at LWA. Natural contributes more to total light extinction than US_Anthro sources and even more combined ammonium nitrate and ammonium sulfate light extinction. Prescribed wildland fires also contribute to light extinction on the clearest days where much of this impairment is from organic mass.

Table 5: LWA 2028OTB Light Extinction on the Clearest Days by Source Category

Source Category	Ammonium Nitrate	Ammonium Sulfate	Coarse Mass	Elemental Carbon	Organic Mass	Sea Salt	Soil	Total	Percent of Total
US_Anthro	0.34	0.64	0.76	0.14	0.24	0.00	0.08	2.20	22%
Int_Anthro	0.77	1.77	0.97	0.31	0.12	0.00	0.13	4.08	41%
Natural	0.41	0.92	0.15	0.08	0.58	0.18	0.00	2.32	23%
US_RxWildlandFire	0.14	0.28	0.03	0.14	0.65	0.00	0.01	1.23	12%
US_WildFire	0.00	0.03	0.01	0.04	0.07	0.00	0.00	0.15	1%
CanMexFire	0.01	0.01	0.00	0.02	0.01	0.00	0.00	0.05	1%
Total	1.66	3.64	1.92	0.72	1.68	0.18	0.23	10.03	100%

A review and breakdown of Table 5 shows the following significant contributors to light extinction. The US_Anthro source category accounts for 22% of the total light extinction on the clearest days at LWA. Much of the total light extinction from US_Anthro is comprised of coarse mass and ammonium sulfate.

US_Anthro coarse mass and ammonium sulfate account for 8% and 6% of the total light extinction, respectively. Int_Anthro accounts for 41% of the total light extinction on the clearest days at LWA. Much of the Int_Anthro total light extinction is from coarse mass, ammonium sulfate, and ammonium nitrate. Int_Anthro coarse mass, ammonium sulfate, and ammonium nitrate account for 10%, 18%, and 8% of the total light extinction, respectively. Unlike the most impaired days, Natural contributes to more impairment than US_Anthro on the clearest days, at 23%. Much of the total light extinction from Natural is comprised of ammonium nitrates at 4%, ammonium sulfates at 9%, and organic mass at 6%. Additionally, on the clearest days, prescribed wildland fires account for 12% of the total light extinction, 6% of which is from organic mass.

Figure 6: TRNP 2028OTB Light Extinction on the Clearest Days by Source Category

Figure 6 shows Int_Anthro ammonium sulfate light extinction is considerably higher than US_Anthro ammonium sulfate extinction on the clearest days at TRNP, this was also true for the most impaired days. US_Anthro ammonium nitrate light extinction is approximately the same as Int_Anthro on the clearest days. Overall, the light extinction from US_Anthro is the greatest, but a significant portion of the light extinction is from coarse mass and organic mass. Combined US_Anthro coarse mass and organic mass contribute more to light extinction on the clearest days than the combined ammonium sulfates and ammonium nitrates. US_Anthro ammonium nitrate and ammonium sulfate light extinction is also less than the contribution from Int_Anthro for these species. Additionally, Natural contributes significantly to the overall light extinction on the clearest days. Natural also contribute more to ammonium sulfate light extinction than US_Anthro sources and over half of the ammonium nitrate light extinction.

Table 6: TRNP 2028OTB Light Extinction on the Clearest Days by Source Category

Source Category	Ammonium Nitrate	Ammonium Sulfate	Coarse Mass	Elemental Carbon	Organic Mass	Sea Salt	Soil	Total	Percent of Total
US_Anthro	0.24	0.62	1.07	0.19	0.55	0.00	0.19	2.86	43%
Int_Anthro	0.35	0.98	0.27	0.11	0.17	0.00	0.05	1.93	29%
Natural	0.16	0.65	0.35	0.01	0.44	0.05	0.00	1.67	25%
US_RxWildlandFire	0.00	0.02	0.00	0.02	0.13	0.00	0.00	0.17	3%
US_WildFire	0.00	0.01	0.00	0.01	0.05	0.00	0.00	0.07	1%
CanMexFire	0.00	0.00	0.00	0.00	0.01	0.00	0.00	0.02	0%
Total	0.75	2.28	1.70	0.34	1.35	0.05	0.25	6.73	100%

A review and breakdown of Table 6 shows the following significant contributors to light extinction. The US_Anthro source category accounts for 43% of the total light extinction on the clearest days at TRNP. Only 13% of the total light extinction from US_Anthro is comprised of ammonium nitrates and ammonium sulfates, 4% and 9%, respectively. Meaning, 30% of the overall light extinction from US_Anthro on the clearest is from coarse mass, elemental carbon, organic mass, and soil. Int_Anthro accounts for 29% of the total light extinction on the clearest days at TRNP. Much of the total light extinction from Int_Anthro is comprised of ammonium nitrates and ammonium sulfates. Int_Anthro ammonium nitrate and ammonium sulfate account for 5% and 15% of the total light extinction, respectively. Natural also contribute a significant amount to impairment on the clearest days, at 25%. Much of the total light extinction from Natural is comprised of ammonium sulfates at 10%, coarse mass at 5%, and organic mass at 7%.

1.2.2 Species Light Extinction on the Clearest Days

Figure 7 and Figure 8 display the 2028OTB source apportionment results for the average of the clearest days for aerosol species within the five major source categories. Table 7 and Table 8 display the numerical data corresponding to Figure 7 and Figure 8 for LWA and TRNP, respectively. The data in these figures and tables is the same as Section 1.2.1. The difference is how the data is displayed. The aerosol species are plotted along the x-axis and the light extinction contribution from the source category is separated by species.

Figure 7: LWA 2028OTB Light Extinction on the Clearest Days by Species

Figure 7 emphasizes a few important items for LWA on the clearest days. Most of the total light extinction comes from ammonium sulfate, followed by ammonium nitrate, organic mass, and coarse mass. For ammonium sulfate and ammonium nitrate, Int_Anthro contributes greater to light extinction than US_Anthro. US_Anthro light extinction contributions from ammonium sulfate, ammonium nitrate, coarse mass, and organic mass are small, each below 1 Mm^{-1} . Natural also contributes significantly to impairment for ammonium sulfate, ammonium nitrate, and organic mass. As noted in the source category breakdown, prescribed wildland fires also account for a sizable portion of the light extinction on the clearest days.

Table 7: LWA 2028OTB Light Extinction on the Clearest Days by Species

Source Category	US_Anthro	Int_Anthro	Natural	US_RxWild landFire	US_Wild Fire	CanMex Fire	Total	Percent of Total
Ammonium Sulfate	0.64	1.77	0.92	0.28	0.03	0.01	3.64	36%
Ammonium Nitrate	0.34	0.77	0.41	0.14	0.00	0.01	1.66	17%
Organic Mass	0.24	0.12	0.58	0.65	0.07	0.01	1.68	17%
Elemental Carbon	0.14	0.31	0.08	0.14	0.04	0.02	0.72	7%

Source Category	US_Anthro	Int_Anthro	Natural	US_RxWild landFire	US_Wild Fire	CanMex Fire	Total	Percent of Total
Coarse Mass	0.76	0.97	0.15	0.03	0.01	0.00	1.92	19%
Sea Salt	0.00	0.00	0.18	0.00	0.00	0.00	0.18	2%
Soil	0.08	0.13	0.00	0.01	0.00	0.00	0.23	2%
Total	2.20	4.08	2.32	1.23	0.15	0.05	10.03	100%

A review and breakdown of Table 7 shows the following significant contributors to light extinction. Ammonium sulfate accounts for 36% of the total light extinction on the clearest days at LWA, where 18% of the total light extinction is from Int_Anthro, 6% is from US_Anthro, and 9% is from Natural. Coarse mass accounts for the largest species of light extinction after ammonium sulfate at 19% of overall light extinction. Coarse mass from Int_Anthro accounts for 10% and US_Anthro accounts for 8%. Ammonium nitrate accounts for 17% of the total light extinction, where 8% of the total light extinction is from Int_Anthro, 3% is from US_Anthro, and 4% is from Natural. Organic mass also accounts for 17% of the total light extinction, where 1% of the total light extinction is from Int_Anthro, 2% is from US_Anthro, 6% is from Natural, and 6% is from prescribed wildland fires.

Figure 8: TRNP 2028OTB Light Extinction on the Clearest Days by Species

Figure 8 emphasizes a few important items for TRNP on the clearest days. Light extinction from ammonium sulfate is the most significant aerosol species and Int_Anthro, US_Anthro, and Natural are

the primary contributors to the ammonium sulfate light extinction. Coarse mass and organic mass are the next largest contributors to light extinction on the clearest days and each of these species contributes more to light extinction than ammonium nitrate.

Table 8: TRNP 2028OTB Light Extinction on the Clearest Days by Species

Source Category	US_Anthro	Int_Anthro	Natural	US_RxWild landFire	US_Wild Fire	CanMex Fire	Total	Percent of Total
Ammonium Sulfate	0.62	0.98	0.65	0.02	0.01	0.00	2.28	34%
Ammonium Nitrate	0.24	0.35	0.16	0.00	0.00	0.00	0.75	11%
Organic Mass	0.55	0.17	0.44	0.13	0.05	0.01	1.35	20%
Elemental Carbon	0.19	0.11	0.01	0.02	0.01	0.00	0.34	5%
Coarse Mass	1.07	0.27	0.35	0.00	0.00	0.00	1.70	25%
Sea Salt	0.00	0.00	0.05	0.00	0.00	0.00	0.05	1%
Soil	0.19	0.05	0.00	0.00	0.00	0.00	0.25	4%
Total	2.86	1.93	1.67	0.17	0.07	0.02	6.73	100%

A review and breakdown of Table 8 shows the following significant contributors to light extinction. Ammonium sulfate accounts for 34% of the total light extinction on the clearest days at TRNP, where 15% of the total light extinction is from Int_Anthro, 9% is from US_Anthro, and 10% is from Natural. Coarse mass accounts for 25% of the total light extinction, where 4% of the total light extinction is from Int_Anthro, 16% is from US_Anthro, and 5% is from Natural. Organic mass accounts for 20% of the total light extinction, where 3% of the total light extinction is from Int_Anthro, 8% is from US_Anthro, and 7% is from Natural. Ammonium nitrate only accounts for 11% of the total light extinction on the clearest days, where 5% of the total light extinction is from Int_Anthro, 4% is from US_Anthro, and 2% is from Natural.

1.2.3 Clearest Days Conclusion

In summary, the contributors to light extinction on the clearest days for both LWA and TRNP come from six main areas: Int_Anthro ammonium sulfate, Int_Anthro ammonium nitrate, US_Anthro ammonium sulfate, US_Anthro ammonium nitrate, Natural ammonium sulfate, and Natural ammonium nitrate. Light extinction from coarse mass and organic mass are also more significant on the clearest days versus the most impaired days. Coarse mass accounts for 19% of the clearest days' total impairment at LWA and 25% of the clearest days' impairment at TRNP. Organic mass accounts for 17% of the clearest days' total impairment at LWA and 20% of the clearest days' total impairment at TRNP.

2 State and Sector Source Impacts on North Dakota Visibility

This section contains the data from the anthropogenic state and sector source apportionment results from the modeling performed by WRAP.⁵ WRAP completed modeling to determine the visibility impacts from emissions of US anthropogenic sources by state and sector. This modeling was completed for the species of ammonium nitrates and ammonium sulfates. The sectors included in the modeling were: EGU, OilGas (oil and gas point and area sources with tribal oil and gas assigned to the state), NonEGU (all other point), Mobile (mobile on-road, non-road, rail, commercial marine vessels), and RemainAnthro (all remaining anthropogenic emissions including fugitive dust, agricultural, agricultural fire, residential wood combustion, and all other remaining nonpoint sources). Each of these sector's impairment contribution was determined on a state basis for the 13 continental WRAP states (no Hawaii or Alaska) and from the remaining continental US "RemUS".

The state and sector level source apportionment results are discussed in Section 2.1 for the most impaired days and Section 2.2 for the clearest days.

The aerosol species which contribute to light extinction are ammonium nitrate, ammonium sulfate, organic mass, elemental carbon, coarse mass, soil, and sea salt. The aerosol species of most significance to North Dakota Class I areas are ammonium nitrate and ammonium sulfate. The aerosol species of ammonium nitrate and ammonium sulfate were the only two species tracked for the state and sector breakdown.

The modeling was completed using the 2028 inventory projection (2028OTB). For details on the 2028OTB emission inventory, see Section 4.1.6 of the main SIP document.

2.1 Most Impaired Days

2.1.1 Ammonium Nitrate Light Extinction on the Most Impaired Days

Figure 9 and Figure 10 display the 2028OTB state and sector apportionment results for the average of the most impaired days at LWA and TRNP for aerosol species of ammonium nitrate within the five sector categories. Results are specific to US anthropogenic (US_Anthro) light extinction only. The five major source categories are: EGU, OilGas, NonEGU, Mobile, and RemainAnthro. Table 9 and Table 10 display the numerical data corresponding to Figure 9 and Figure 10 for LWA and TRNP, respectively.

⁵ Available at:

https://views.cira.colostate.edu/docs/iwdw/platformdocs/WRAP_2014/SourceApportionmentSpecifications_WRA_P_RepBase2_and_2028OTBa2_High-LevelPMandO3_and_Low-Level_PM_andOptionalO3_Sept29_2020.pdf (Last visited February 22, 2021)

Figure 9: LWA Ammonium Nitrate light Extinction on the Most Impaired Days

Figure 9 shows that much of the projected US anthropogenic ammonium nitrate light extinction at LWA on the most impaired days comes from sources within North Dakota. The primary sectors contributing to the light extinction are OilGas, EGU and Mobile.

Table 9: LWA Ammonium Nitrate light Extinction on the Most Impaired Days

State	EGU	OilGas	Mobile	NonEGU	RemainAnthro	Total	Percent of Total
ND	0.59	3.91	0.63	0.06	0.07	5.26	73%
AZ	0.00	0.00	0.02	0.00	0.00	0.03	0%
CA	0.00	0.00	0.04	0.02	0.02	0.08	1%
CO	0.01	0.03	0.03	0.01	0.01	0.09	1%
ID	0.00	0.00	0.03	0.01	0.01	0.05	1%
MT	0.14	0.06	0.23	0.05	0.05	0.54	7%
NM	0.00	0.01	0.00	0.00	0.00	0.02	0%
NV	0.00	0.00	0.01	0.00	0.00	0.02	0%
OR	0.00	0.00	0.01	0.01	0.00	0.02	0%
SD	0.00	0.01	0.07	0.01	0.01	0.10	1%
UT	0.04	0.02	0.06	0.02	0.02	0.16	2%
WA	0.00	0.00	0.03	0.01	0.01	0.05	1%
WY	0.09	0.09	0.09	0.09	0.01	0.36	5%
RemUS	0.08	0.06	0.20	0.03	0.05	0.42	6%

State	EGU	OilGas	Mobile	NonEGU	RemainAnthro	Total	Percent of Total
Total	0.98	4.19	1.45	0.34	0.26	7.21	100%

Table 9 shows the state and source category breakdown of ammonium nitrate light extinction contributions on the most impaired days at LWA. North Dakota sources contribute 73% of the total US_Anthro ammonium nitrate light extinction at LWA on the most impaired days. The remaining 27% primarily comes from MT (7%), WY (5%), and RemUS (6%) with all other continental US WRAP states accounting for the remaining 9%. None of the impairment from US sources outside North Dakota is considered significant. The outside impairment is small on a relative or percentage basis, less than 10%. On an overall magnitude basis, US_Anthro impairment from outside of ND is also small. The highest state modeled impairment comes from MT and is 0.54 Mm⁻¹.

North Dakota's 73% contribution is mostly from three sectors, OilGas, EGU, and Mobile. Of the North Dakota contribution, OilGas accounts for 54% of the total US_Anthro light extinction, EGU accounts for 8%, and Mobile accounts for 9%. On a relative basis OilGas accounts for over half of the US_Anthro ammonium nitrate light extinction at LWA. However, the magnitude of the projected OilGas impairment is relatively small at only 3.91 Mm⁻¹, compared to the overall species light extinction of 39.45 Mm⁻¹ (Section 1.1) or the total light extinction of 50.45 Mm⁻¹ (Section 3.1 of the main SIP document). The magnitude of ammonium nitrate impairment from North Dakota EGUs and Mobile sources is even smaller, where EGUs contribute 0.59 Mm⁻¹ of light extinction and Mobile contributes 0.63 Mm⁻¹.

Figure 10: TRNP Ammonium Nitrate light Extinction on the Most Impaired Days

Similar to LWA, Figure 10 shows that the majority of projected US anthropogenic ammonium nitrate light extinction at TRNP on the most impaired days comes from sources within North Dakota. The primary sectors contributing to the light extinction are OilGas, EGU and Mobile.

Table 10: TRNP Ammonium Nitrate light Extinction on the Most Impaired Days

State	EGU	OilGas	Mobile	NonEGU	RemainAnthro	Total	Percent of Total
ND	0.15	2.02	0.49	0.03	0.03	2.71	64%
AZ	0.00	0.00	0.00	0.00	0.00	0.00	0%
CA	0.00	0.00	0.02	0.01	0.01	0.05	1%
CO	0.01	0.02	0.02	0.01	0.01	0.06	1%
ID	0.00	0.00	0.02	0.01	0.01	0.04	1%
MT	0.07	0.12	0.29	0.04	0.05	0.57	13%
NM	0.00	0.00	0.00	0.00	0.00	0.00	0%
NV	0.00	0.00	0.01	0.00	0.00	0.01	0%
OR	0.00	0.00	0.01	0.01	0.00	0.02	1%
SD	0.00	0.02	0.06	0.01	0.01	0.09	2%
UT	0.01	0.01	0.02	0.01	0.00	0.05	1%
WA	0.00	0.00	0.03	0.01	0.01	0.05	1%
WY	0.10	0.09	0.08	0.09	0.01	0.37	9%
RemUS	0.02	0.03	0.12	0.03	0.02	0.22	5%

State	EGU	OilGas	Mobile	NonEGU	RemainAnthro	Total	Percent of Total
Total	0.37	2.31	1.18	0.26	0.15	4.26	100%

Table 10 shows the state and source category breakdown of ammonium nitrate light extinction contributions on the most impaired days at TRNP. North Dakota sources contribute 64% of the total US_Anthro ammonium nitrate light extinction at TRNP on the most impaired days. The remaining 36% primarily comes from MT (13%), WY (9%), and RemUS (5%) with all other continental US WRAP states accounting for the remaining 9%. None of the impairment from US sources outside North Dakota is considered significant. On an overall magnitude basis, US_Anthro impairment from outside of ND is small. The highest state modeled impairment comes from MT and is 0.57 Mm^{-1} .

North Dakota's 64% contribution is mostly from three sectors, OilGas, EGU, and Mobile. Of the North Dakota contribution, OilGas accounts for 47% of the total US_Anthro light extinction, EGU accounts for 4%, and Mobile accounts for 12%. On a relative basis OilGas accounts for almost half of the US_Anthro ammonium nitrate light extinction at TRNP. However, the magnitude of the projected OilGas impairment is relatively small at only 2.02 Mm^{-1} , compared to the overall species light extinction of 29.72 Mm^{-1} (Section 1.1) or the total light extinction of 40.72 Mm^{-1} (Section 3.1 of the main SIP document). The magnitude of ammonium nitrate impairment from North Dakota EGUs and Mobile sources is even smaller, where EGUs contribute 0.15 Mm^{-1} of light extinction and Mobile contributes 0.49 Mm^{-1} .

2.1.2 Ammonium Sulfate Light Extinction on the Most Impaired Days

Figure 11 and Figure 12 display the 2028OTB state and sector apportionment results for the average of the most impaired days for aerosol species of ammonium sulfate within the five sector categories. Results are specific to modeled US anthropogenic light extinction only. The five major source categories are: EGU, OilGas, NonEGU, Mobile, and RemainAnthro. Table 11 and Table 12 display the numerical data corresponding to Figure 11 and Figure 12 for LWA and TRNP, respectively.

Figure 11: LWA Ammonium Sulfate light Extinction on the Most Impaired Days

Figure 11 shows that much of the modeled US anthropogenic ammonium sulfate light extinction at LWA on the most impaired days comes from sources within North Dakota. The primary sectors contributing to the light extinction are OilGas and EGU.

Table 11: LWA Ammonium Sulfate light Extinction on the Most Impaired Days

State	EGU	OilGas	Mobile	NonEGU	RemainAnthro	Total	Percent of Total
ND	1.97	2.79	0.01	0.05	0.03	4.85	81%
AZ	0.00	0.00	0.00	0.01	0.00	0.01	0%
CA	0.00	0.00	0.00	0.02	0.01	0.03	0%
CO	0.01	0.00	0.00	0.01	0.00	0.02	0%
ID	0.00	0.00	0.00	0.02	0.00	0.03	0%

WA	0.00	0.00	0.00	0.04	0.01	0.04	1%
WY	0.15	0.03	0.00	0.06	0.00	0.25	4%
RemUS	0.19	0.00	0.00	0.03	0.02	0.25	4%

State	EGU	OilGas	Mobile	NonEGU	RemainAnthro	Total	Percent of Total
Total	2.59	2.89	0.03	0.32	0.15	5.98	100%

Table 11 shows the state and source category breakdown of ammonium sulfate light extinction contributions on the most impaired days at LWA. North Dakota sources contribute 81% of the total US_Anthro ammonium sulfate light extinction at LWA on the most impaired days. The remaining 19% primarily comes from MT (7%), WY (4%), and RemUS (4%) with all other continental US WRAP states accounting for the remaining 4%. None of the impairment from US sources outside North Dakota is considered significant. The outside impairment is small on a relative or percentage basis, less than 10%. On an overall magnitude basis, US_Anthro impairment from outside of ND is small. The highest state modeled impairment comes from MT and is 0.41 Mm^{-1} .

North Dakota's 81% contribution is mostly from two sectors, OilGas and EGU. Of the North Dakota contribution, OilGas accounts for 47% of the total US_Anthro light extinction and EGU accounts for 33%. On a relative basis OilGas accounts for nearly half of the US_Anthro ammonium sulfate light extinction at LWA. However, the magnitude of the projected OilGas impairment is relatively small at only 2.79 Mm^{-1} , compared to the overall species light extinction of 39.45 Mm^{-1} (Section 1.1) or the total light extinction of 50.45 Mm^{-1} (Section 3.1 of the main SIP document). The magnitude of ammonium sulfate impairment from North Dakota EGUs is even smaller, where EGUs contribute 1.97 Mm^{-1} of light extinction.

Figure 12: TRNP Ammonium Sulfate light Extinction on the Most Impaired Days

Figure 12 shows that the majority of projected US anthropogenic ammonium sulfate light extinction at TRNP on the most impaired days comes from sources within North Dakota. The primary sectors contributing to the light extinction are OilGas and EGU.

Table 12: TRNP Ammonium Sulfate light Extinction on the Most Impaired Days

State	EGU	OilGas	Mobile	NonEGU	RemainAnthro	Total	Percent of Total
ND	0.70	1.57	0.03	0.02	0.02	2.34	69%
AZ	0.00	0.00	0.00	0.00	0.00	0.00	0%

NV	0.01	0.00	0.00	0.00	0.00	0.01	0%
OR	0.00	0.00	0.00	0.00	0.00	0.01	0%
SD	0.00	0.01	0.00	0.01	0.00	0.02	1%
UT	0.01	0.00	0.00	0.00	0.00	0.02	0%
WA	0.00	0.00	0.00	0.04	0.01	0.06	2%
WY	0.25	0.06	0.00	0.05	0.00	0.36	11%
RemUS	0.06	0.00	0.00	0.02	0.01	0.09	3%
Total	1.25	1.72	0.04	0.26	0.14	3.40	100%

Table 12 shows the state and source category breakdown of ammonium sulfate light extinction contributions on the most impaired days at TRNP. North Dakota sources contribute 69% of the total US_Anthro ammonium sulfate light extinction at LWA on the most impaired days. The remaining 31% primarily comes from MT (13%), WY (11%), and RemUS (3%) with all other continental US WRAP states accounting for the remaining 4%. None of the impairment from US sources outside North Dakota is considered significant. On an overall magnitude basis, US_Anthro impairment from outside of ND is small. The highest state modeled impairment comes from MT and is 0.45 Mm^{-1} .

North Dakota's 69% contribution is mostly from two sectors, OilGas and EGU. Of the North Dakota contribution, OilGas accounts for 46% of the total US_Anthro light extinction and EGU accounts for 20%. On a relative basis OilGas accounts for nearly half of the US_Anthro ammonium sulfate light extinction at TRNP. However, the magnitude of the projected OilGas impairment is relatively small at only 1.57 Mm^{-1} , compared to the overall species light extinction of 29.72 Mm^{-1} (Section 1.1) or the total light extinction of 40.72 Mm^{-1} (Section 3.1 of the main SIP document). The magnitude of ammonium sulfate impairment from North Dakota EGUs is even smaller, where EGUs contribute 0.70 Mm^{-1} of light extinction.

2.1.3 North Dakota Sector Contribution on the Most Impaired Days

The impairment caused by North Dakota sectors can also be compared to the overall species light extinction projection for 2028. The following is a breakdown of species light extinction: US anthropogenic (US_Anthro), International anthropogenic (Int_Anthro), Natural, prescribed wildland fire (US_RxWildlandFire), US wildfire, and Canada Mexico Fires (CanMexFire) is discussed in detail and is included in Section 1.1. The following breakdown shows the impairment caused by the North Dakota sectors as compared to the species light extinction for the 2028OTB scenario. US_Anthro sources have been broken down into the following sectors: North Dakota electrical generating utilities (ND EGU); North Dakota Oil and Gas point and area sources including tribal Oil and Gas operation (ND OilGas); North Dakota mobile onroad, non-road, rail, and commercial marine vessels (ND Mobile); Other North Dakota point sources (ND NonEGU); all remaining anthropogenic emissions including fugitive dust, agriculture, agricultural fire, residential wood combustion, and all remaining nonpoint sources (ND RemainAnthro); all US_Anthro minus the North Dakota sectors (Remaining US); and the Boundary Conditions from US emissions (BCUS). The species breakdown for all US_Anthro sources and sectors was limited to ammonium nitrate and ammonium sulfate. Therefore, impairment from the species of coarse mass, elemental carbon, organic mass, sea salt, and soil for all US_Anthro sources (including North Dakota sources) are included in the “Remaining US” row for Table 13 and Table 14. Note that Tribal oil and gas emissions are assigned to the ND OilGas category.

Table 13: LWA Sector and Source Category Contributions to Species Light Extinction on MID

Source Category/Sector	Ammonium Nitrate	Ammonium Sulfate	Coarse Mass	Elemental Carbon	Organic Mass	Sea Salt	Soil	Grand Total
ND EGU	2%	5%	--	--	--	--	--	7%
ND OilGas	10%	7%	--	--	--	--	--	17%
ND Mobile	2%	0%	--	--	--	--	--	2%
ND NonEGU	0%	0%	--	--	--	--	--	0%
ND RemainAnthro	0%	0%	--	--	--	--	--	0%
Remaining US	5%	3%	2%	1%	3%	0%	0%	15%
BCUS	0%	0%	--	--	--	--	--	1%
Int_Anthro	19%	17%	1%	2%	1%	0%	0%	40%
CanMexFire	0%	0%	0%	0%	0%	0%	0%	1%
Natural	7%	5%	1%	0%	2%	1%	0%	16%
US_RxWildlandFire	0%	0%	0%	0%	1%	0%	0%	1%
US_WildFire	0%	0%	0%	0%	0%	0%	0%	0%
Grand Total	45%	38%	5%	4%	7%	1%	1%	100%

Table 13 shows the percent breakdown of the total species light extinction contributions from different source categories and sectors at LWA. US_Anthro sources contribute to 42% of the total light extinction, with 19% and 16% attributed to ammonium nitrate and ammonium sulfate, respectively. ND sectors contribute to 26% of the total light extinction. The largest source category contributor is ND OilGas at

17%, with ND EGU being less than half of that at a 7% contribution. Similar to US_Anthro, Int_Anthro contributes 40% to the total light extinction. The only other significant contributor outside of these is Natural at 16%.

ND OilGas light extinction consists of North Dakota point and area sources and tribal oil and gas operations. North Dakota area oil and gas sources (upstream development and operation) consists of over 15,000 individual wells spread out amongst over 8,000 sites. Meaning the 17% combined ammonium nitrate and ammonium sulfate impairment comes from many individual sources, and a significant portion (tribal oil and gas) is outside of the State of North Dakota's control. The largest point sources emitters were evaluated under the four-factor analysis (Section 5.2 of the main SIP document).

Table 14: TRNP Sector and Source Category Contributions to Species Light Extinction on MID

Source Category/Sector	Ammonium Nitrate	Ammonium Sulfate	Coarse Mass	Elemental Carbon	Organic Mass	Sea Salt	Soil	Grand Total
ND EGU	1%	2%	--	--	--	--	--	3%
ND OilGas	7%	5%	--	--	--	--	--	12%
ND Mobile	2%	0%	--	--	--	--	--	2%
ND NonEGU	0%	0%	--	--	--	--	--	0%
ND RemainAnthro	0%	0%	--	--	--	--	--	0%
Remaining US	5%	4%	4%	1%	4%	0%	1%	19%
BCUS	1%	1%	--	--	--	--	--	1%
Int_Anthro	15%	24%	2%	1%	1%	0%	0%	43%
CanMexFire	0%	0%	0%	0%	0%	0%	0%	0%
Natural	5%	8%	1%	0%	2%	1%	0%	18%
US_RxWildlandFire	0%	0%	0%	0%	0%	0%	0%	1%
US_WildFire	0%	0%	0%	0%	0%	0%	0%	1%
Grand Total	36%	45%	7%	3%	8%	1%	1%	100%

Table 14 shows the percent breakdown of the total species light extinction contributions from different source categories and sectors at TRNP. US_Anthro sources contribute to 37% of the total light extinction, with 15% and 12% attributed to ammonium nitrate and ammonium sulfate, respectively. ND sectors contribute to 17% of the total light extinction. The largest source category contributor is ND OilGas at 12%, with ND EGU being a quarter of that at a 3% contribution. Int_Anthro has a higher contribution than US_Anthro, contributing 43% to the total light extinction. The only other significant contributor outside of these is Natural at 18%.

2.2 Clearest Days

2.2.1 Ammonium Nitrate Light Extinction on the Clearest Days

Figure 13: LWA Ammonium Nitrate light Extinction on the Clearest Days

Figure 13 shows that the majority of projected US anthropogenic ammonium nitrate light extinction at LWA on the clearest days comes from sources within North Dakota.

Table 15: LWA Ammonium Nitrate light Extinction on the Clearest Days

State	EGU	OilGas	Mobile	NonEGU	RemainAnthro	Total	Percent of Total

Total	0.01	0.18	0.07	0.01	0.01	0.29	100%

Table 15 shows the state and source category breakdown of ammonium nitrate light extinction contributions on the clearest days at LWA. North Dakota sources contribute 70% of the total US_Anthro ammonium nitrate light extinction at LWA on the clearest days. The remaining 30% primarily comes from MT (17%) and RemUS (7%), with all other continental US WRAP states accounting for the remaining 6%. None of the impairment from US sources outside North Dakota is considered significant. On an overall magnitude basis, US_Anthro impairment from outside of ND is small. The highest state modeled impairment comes from MT and is 0.05 Mm^{-1} .

North Dakota's 70% contribution is mostly from two sectors, OilGas and Mobile. Of the North Dakota contribution, OilGas accounts for 58% of the total US_Anthro light extinction and Mobile accounts for 9%. On a relative basis OilGas accounts for over half of the US_Anthro ammonium nitrate light extinction at LWA on the clearest days. However, the magnitude of the projected OilGas impairment is small at only 0.17 Mm^{-1} . The magnitude of ammonium nitrate impairment from North Dakota Mobile is even smaller, where Mobile contributes 0.03 Mm^{-1} of light extinction.

Figure 14: TRNP Ammonium Nitrate light Extinction on the Clearest Days

Figure 14 shows that the majority of projected US anthropogenic ammonium nitrate light extinction at TRNP on the clearest days comes from sources within North Dakota.

Total	0.03	0.08	0.09	0.02	0.01	0.23	100%

Table 16 shows the state and source category breakdown of ammonium nitrate light extinction contributions on the clearest days at TRNP. North Dakota sources contribute 38% of the total US_Anthro ammonium nitrate light extinction at TRNP on the clearest days, with Montana sources contributing 34%. The remaining 28% primarily comes from WY (15%), with all other continental US WRAP states accounting for the remaining 13%. On an overall magnitude basis, US_Anthro impairment from outside of ND is small. The highest state modeled impairment from MT is 0.08 Mm⁻¹.

North Dakota's 38% contribution is mostly from two sectors, OilGas and Mobile. Of the North Dakota contribution, OilGas accounts for 26% of the total US_Anthro light extinction and Mobile accounts for 11%. The magnitude of the projected OilGas impairment is small at only 0.06 Mm⁻¹. The magnitude of ammonium nitrate impairment from North Dakota Mobile is even smaller, where Mobile contributes 0.03 Mm⁻¹ of light extinction.

2.2.2 Ammonium Sulfate Light Extinction on the Clearest Days

Figure 15: LWA Ammonium Sulfate light Extinction on the Clearest Days

Figure 15 shows that the vast majority of projected US anthropogenic ammonium sulfate light extinction at LWA on the clearest days comes from sources within North Dakota. The primary sectors contributing to the light extinction are OilGas and EGU.

Table 17: LWA Ammonium Sulfate light Extinction on the Clearest Days

State	EGU	OilGas	Mobile	NonEGU	RemainAnthro	Total	Percent of Total
ND	0.09	0.31	0.00	0.00	0.00	0.41	78%
AZ	0.00	0.00	0.00	0.00	0.00	0.00	0%

CA	0.00	0.00	0.00	0.00	0.00	0.01	1%
CO	0.00	0.00	0.00	0.00	0.00	0.00	0%
ID	0.00	0.00	0.00	0.01	0.00	0.01	2%
MT	0.07	0.04	0.00	0.04	0.02	0.17	30%
NM	0.00	0.00	0.00	0.00	0.00	0.00	0%
NV	0.00	0.00	0.00	0.00	0.00	0.01	1%
OR	0.00	0.00	0.00	0.00	0.00	0.00	0%
SD	0.00	0.00	0.00	0.00	0.00	0.00	0%
UT	0.00	0.00	0.00	0.00	0.00	0.00	1%
WA	0.00	0.00	0.00	0.01	0.00	0.01	2%
WY	0.02	0.01	0.00	0.00	0.00	0.03	5%
RemUS	0.00	0.00	0.00	0.00	0.00	0.01	1%
Total	0.10	0.35	0.01	0.07	0.04	0.58	100%

Table 18 shows the state and source category breakdown of ammonium sulfate light extinction contributions on the clearest days at TRNP. North Dakota sources contribute 56% of the total US_Anthro ammonium sulfate light extinction at TRNP on the clearest days, with Montana sources contributing 30%. The remaining 14% primarily comes from WY (5%), with all other continental US WRAP states accounting for the remaining 9%. On an overall magnitude basis, US_Anthro impairment from outside of ND is small. The highest state modeled impairment from MT is 0.17 Mm⁻¹.

North Dakota's 56% contribution is mostly from the OilGas sector. Of the North Dakota contribution, OilGas accounts for 52% of the total US_Anthro light extinction. The magnitude of the projected OilGas impairment is small at only 0.30 Mm⁻¹.

2.2.3 North Dakota Sector Contribution on the Clearest Days

The impairment caused by North Dakota sectors can also be compared to the overall species light extinction projection for 2028. The following is a breakdown of species light extinction: US anthropogenic (US_Anthro), International anthropogenic (Int_Anthro), Natural, prescribed wildland fire (US_RxWildlandFire), US wildfire, and Canada Mexico Fires (CanMexFire) is discussed in detail and is included in Section 1.2. The following breakdown shows the impairment caused by the North Dakota sectors as compared to the species light extinction for the 2028OTB scenario. US_Anthro sources have been broken down into the following sectors: North Dakota electrical generating utilities (ND EGU);

North Dakota Oil and Gas point and area sources (ND OilGas); North Dakota mobile onroad, non-road, rail, and commercial marine vessels (ND Mobile); Other North Dakota point sources (ND NonEGU); all remaining anthropogenic emissions including fugitive dust, agriculture, agricultural fire, residential wood combustion, and all remaining nonpoint sources (ND RemainAnthro); all US_Anthro minus the North Dakota sectors (Remaining US); and the Boundary Conditions from US emissions (BCUS). The species breakdown for all US_Anthro sources and sectors was limited to ammonium nitrate and ammonium sulfate. Therefore, impairment from the species of coarse mass, elemental carbon, organic mass, sea salt, and soil for all US_Anthro sources (including North Dakota sources) are included in the “Remaining US” row for Table 19 and Table 20. Note that Tribal oil and gas emissions are assigned to the ND OilGas category.

Table 19: LWA Sector and Source Category Contributions to Species Light Extinction on Clearest Days

Sector	Ammonium Nitrate	Ammonium Sulfate	Coarse Mass	Elemental Carbon	Organic Mass	Sea Salt	Soil	Grand Total
ND EGU	0%	1%	--	--	--	--	--	1%
ND OilGas	2%	3%	--	--	--	--	--	5%
ND Mobile	0%	0%	--	--	--	--	--	0%
ND NonEGU	0%	0%	--	--	--	--	--	0%
ND RemainAnthroND	1%	1%	--	--	--	--	--	1%
Remaining US	1%	1%	8%	1%	2%	0%	1%	14%
BCUS	0%	0%	--	--	--	--	--	0%
Int_Anthro	8%	18%	10%	3%	1%	0%	1%	41%
CanMexFire	0%	0%	0%	0%	0%	0%	0%	1%
Natural	4%	9%	1%	1%	6%	2%	0%	23%
US_RxWildlandFire	1%	3%	0%	1%	6%	0%	0%	12%
US_WildFire	0%	0%	0%	0%	1%	0%	0%	1%
Grand Total	17%	36%	19%	7%	17%	2%	2%	100%

Table 19 shows the percent breakdown of the total species light extinction contributions from different source categories and sectors at LWA. US_Anthro sources contribute to 22% of the total light extinction, with approximately 3% and 6% attributed to ammonium nitrate and ammonium sulfate, respectively. ND sectors contribute to 7% of the species light extinction. The largest source category contributor is ND OilGas at 5%, with ND EGU being approximately 1%. Int_Anthro contributes 41% to the species light extinction. The other significant contributors outside of these is Natural at 23% and prescribed fires at 12%.

Table 20: TRNP Sector and Source Category Contributions to Species Light Extinction on Clearest Days

Sector	Ammonium Nitrate	Ammonium Sulfate	Coarse Mass	Elemental Carbon	Organic Mass	Sea Salt	Soil	Grand Total
ND EGU	0%	0%	--	--	--	--	--	0%
ND OilGas	1%	5%	--	--	--	--	--	5%
ND Mobile	0%	0%	--	--	--	--	--	0%
ND NonEGU	0%	0%	--	--	--	--	--	0%
ND RemainAnthroND	0%	0%	--	--	--	--	--	1%
Remaining US	2%	4%	16%	3%	8%	0%	3%	36%
BCUS	0%	0%	--	--	--	--	--	0%
Int_Anthro	5%	15%	4%	2%	3%	0%	1%	29%
CanMexFire	0%	0%	0%	0%	0%	0%	0%	0%
Natural	2%	10%	5%	0%	7%	1%	0%	25%
US_RxWildlandFire	0%	0%	0%	0%	2%	0%	0%	3%
US_WildFire	0%	0%	0%	0%	1%	0%	0%	1%
Grand Total	11%	34%	25%	5%	20%	1%	4%	100%

Table 20 shows the percent breakdown of the total species light extinction contributions from different source categories and sectors at TRNP. US_Anthro sources contribute to 42% of the species light extinction, with approximately 4% and 9% attributed to ammonium nitrate and ammonium sulfate, respectively. ND sectors only contribute to 7% of the species light extinction. The largest source category contributor is ND OilGas at 5%, with ND EGU being less than 1%. Int_Anthro contributes 29% to the species light extinction. The other significant contributor outside of these is Natural at 25%.

C.3 – Weighted Emissions Potential and Area of Influence Summary Results

1 Introduction and Background

Weighted Emissions Potential (WEP) and Area of Influence (AOI) products were made available for Regional Haze planning uses in the western U.S. The analysis was performed for the Most Impaired Days (MID) during each year of the 5-year period from 2014 through 2018 at 76 IMPROVE monitoring sites representing 116 Class I Areas (CIAs) in the 13 states of the contiguous WESTAR-WRAP region and neighboring states. The results were calculated for the 12WUS2 modeling domain aggregated to 36-kilometer resolution. Plots were provided for the 100m and 1000m trajectory heights and for a combined analysis in which data from all four trajectory heights were aggregated. For the purpose of this document the Department evaluated the combined analysis. Emissions originating from outside the 12WUS2 modeling domain were not included in this analysis. For example, the emissions from the nearby Canadian Electric Generating Units (EGU) are included but impacts from the Canadian oil sands are not. See Section 4.7 of the SIP for discussion on emissions from Canadian sources. International emissions were not placed into source categories and are only shown in Total Anthropogenic WEP figures.

The WEP is obtained by overlaying the extinction weighted residence time (EWRT) results with 2028 OTB emissions of light extinction precursors. The results were then normalized by the sum of the WEP for the total anthropogenic emissions. The dark green and light green isopleths in the WEP plots correspond to the 0.5 and 0.1 percent frequency, respectively, from the corresponding EWRT. This document shows the WEP analysis for nitrogen oxides (NO_x) and sulfur dioxide (SO_2) at each North Dakota and nearby CIA for five source sectors: Total Anthropogenic, Oil and Gas, EGUs, On-road mobile, and off highway mobile (Non-road). For each CIA, SO_2 for the on-road and off highway source sectors provided negligible results and were not included.

Complete species, including organic aerosol and elemental carbon, can be found for each western CIAs through the WRAP Technical Support System webpage.¹

2 North Dakota

2.1 Theodore Roosevelt National Park

Figures 1 through 4 shows the WEP results for Theodore Roosevelt National Park.

¹ Available at: <https://views.cira.colostate.edu/tssv2/WEP-AOI/> (Last Visited December 30, 2020)

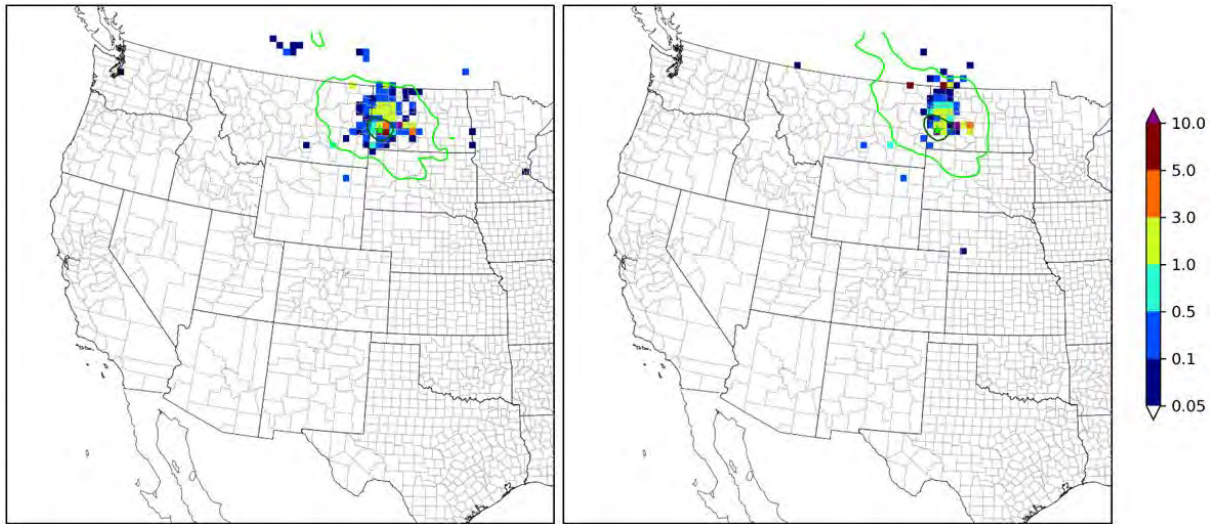

Figure 1: Total Anthropogenic WEP for NO_x (left) and SO₂ (right)

Figure 1 displays the NO_x and SO₂ WEP for total anthropogenic emissions. Most potential anthropogenic impairment comes from sources within North Dakota. A few areas outside of North Dakota show up at minimal levels, none of which were large enough to warrant additional review from North Dakota.

It is difficult to determine any individual sector impacts when looking at all source sectors combined, therefore, Figures 2 through 4 have been provided to show the results at the source category level for Theodore Roosevelt National Park.

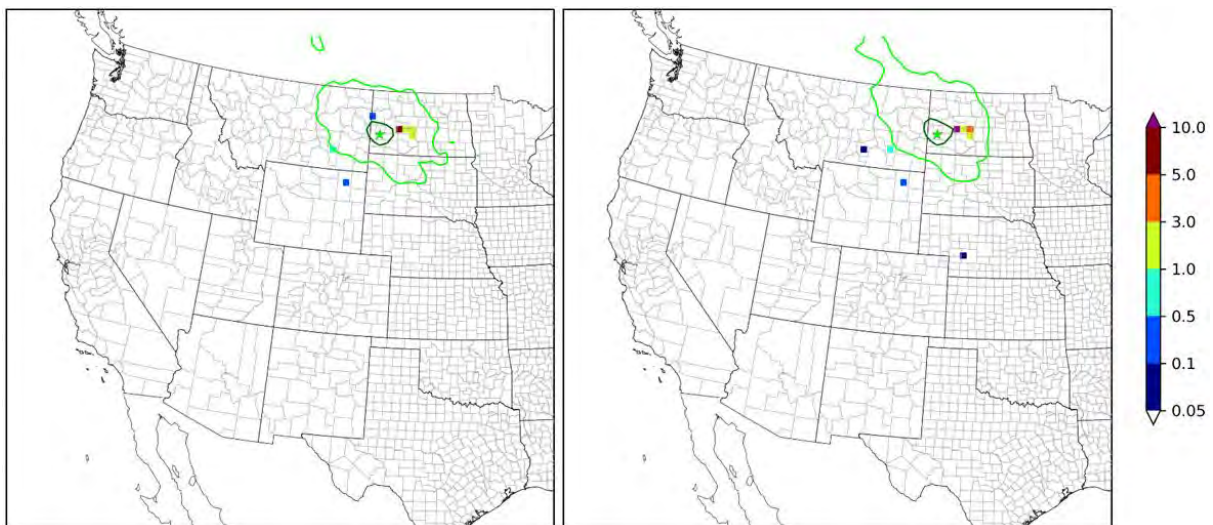

Figure 2: EGU WEP for NO_x (left) and SO₂ (right)

As displayed in Figure 2, most of the potential EGU impairment comes from sources within North Dakota. The potential impairment contribution from EGUs outside of the state were too minor to warrant further review from North Dakota during this planning period. Emissions from North Dakota EGU activity are included in Section 4.2.1 of the SIP.

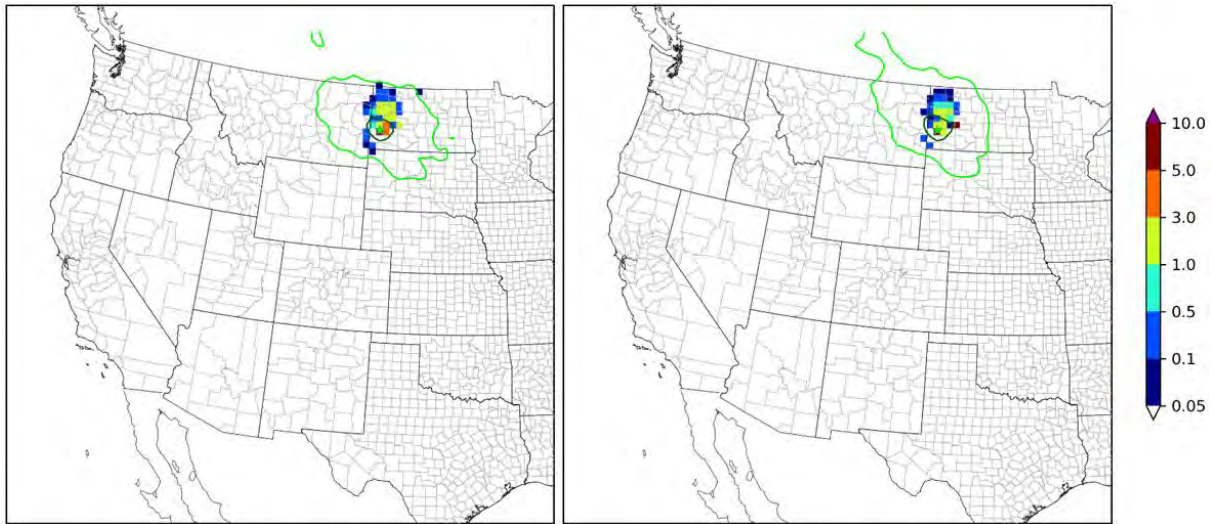

Figure 3: Oil and Gas WEI for NO_x (left) and SO_2 (right)

Figure 3 indicates that the potential impairment from the oil and gas sector comes from sources located within the state, with some very minor potential contributions along the Montana border. As such, oil and gas sources outside of the state did not warrant further review. Emissions from North Dakota oil and gas activity are included in Section 4.3.1 of the SIP. North Dakota is monitoring the development of the oil and gas field and will address impacts from this sector in future planning periods, as needed.

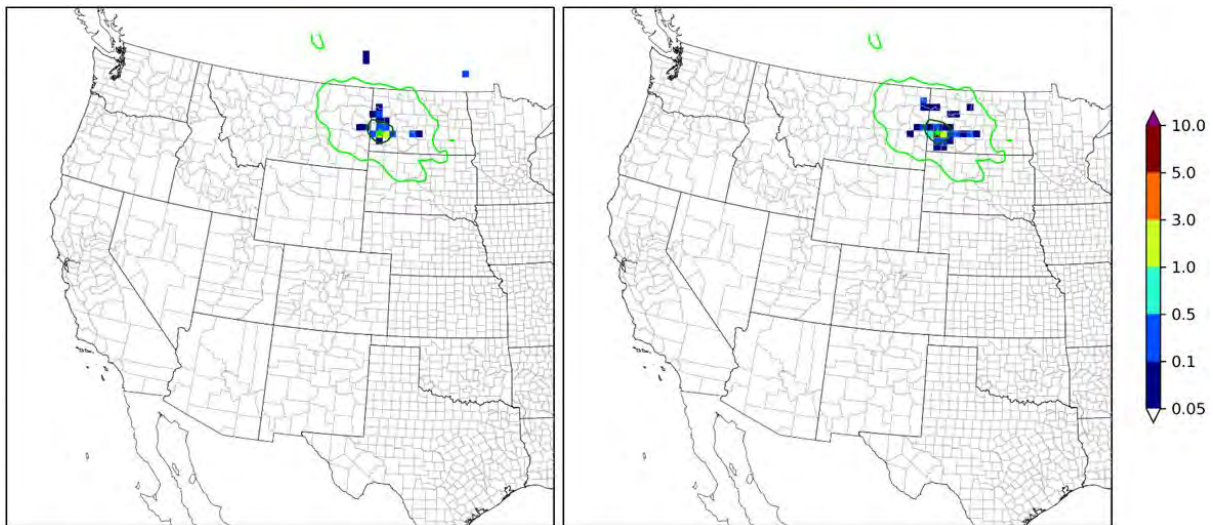

Figure 4: On-road (left) and Non-road (right) WEI for NO_x

Figure 4 shows that the contributions of the on-road and non-road sectors to potential impairment are minimal. As expected, much of the potential contribution follows the main transportation corridor in North Dakota, Interstate 94. Emissions from North Dakota non-road and on-road sectors are included in Section 4.4 and Section 4.5, respectively, in the SIP. The basis of the 2028 OTB mobile source emission inventories utilized both the WRAP 2014NEIv2 dataset as well as the 2014-2016 National Emissions

Modeling Collaborative 2016v1 future year 2028 inventory, with revisions per state agency input. North Dakota did not have any suggested changes to this dataset.

2.2 Lostwood National Wildlife Refuge

Figures 5 through 8 shows the WEP results for Lostwood National Wildlife Refuge.

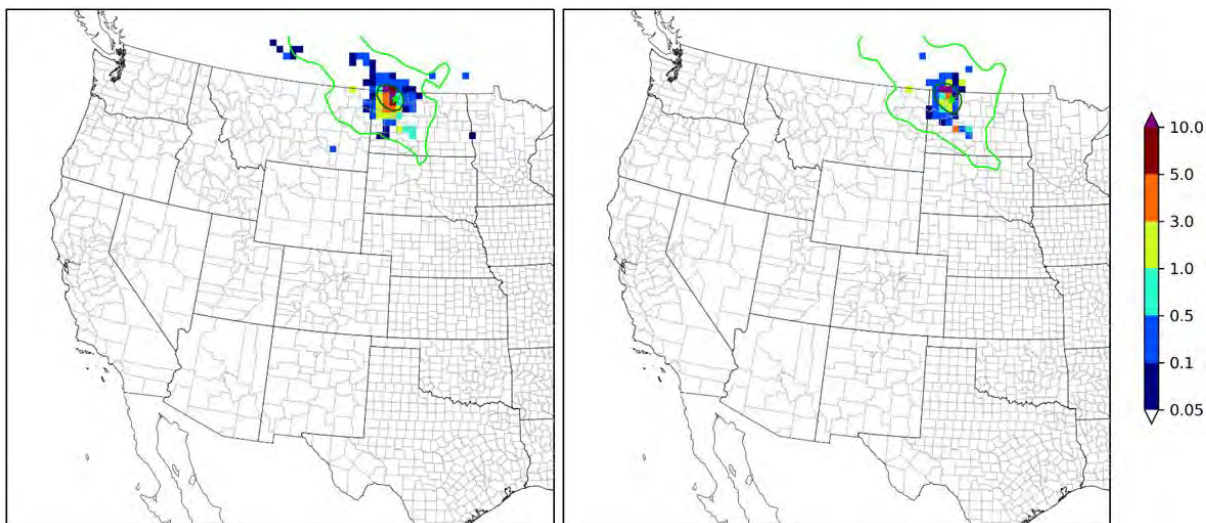

Figure 5: Total Anthropogenic WEP for NO_x (left) and SO₂ (right)

Figure 5 displays the NO_x and SO₂ WEP for total anthropogenic emissions. Most potential anthropogenic impairment comes from sources within North Dakota and just north of the Canadian border. International contributions are not able to be addressed. Potential impairment from Montana source's is minimal, not warranting additional review.

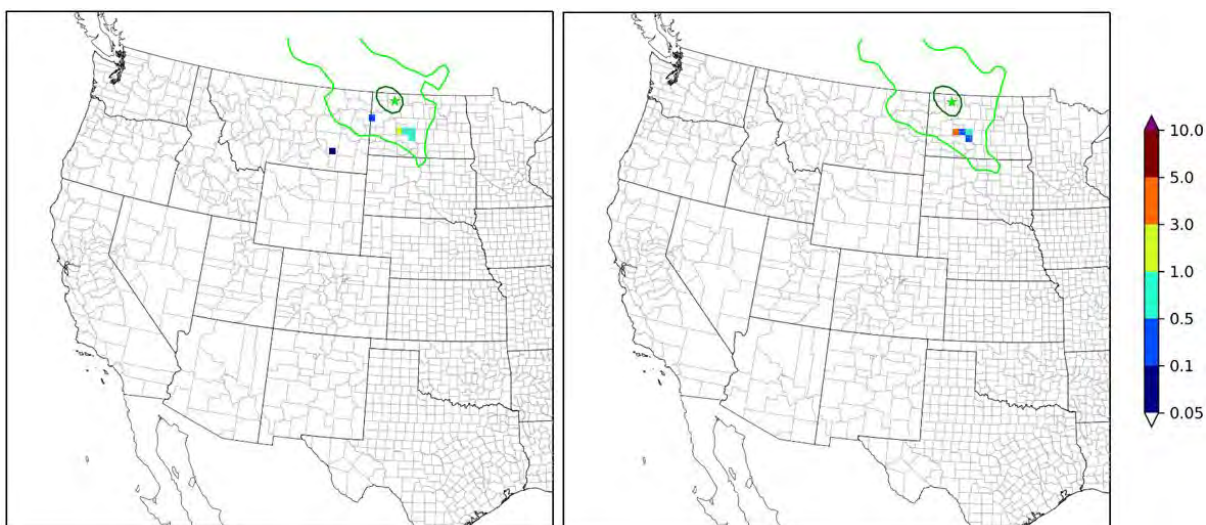

Figure 6: EGU WEP for NO_x (left) and SO₂ (right)

Figure 6 shows that the only EGU sources with an impairment potential that warrants review are located within North Dakota. The potential impairment contribution from EGUs outside of the state were too minor to warrant further review from North Dakota during this planning period. Emissions from North Dakota EGUs are included in Section 4.2.1 of the SIP.

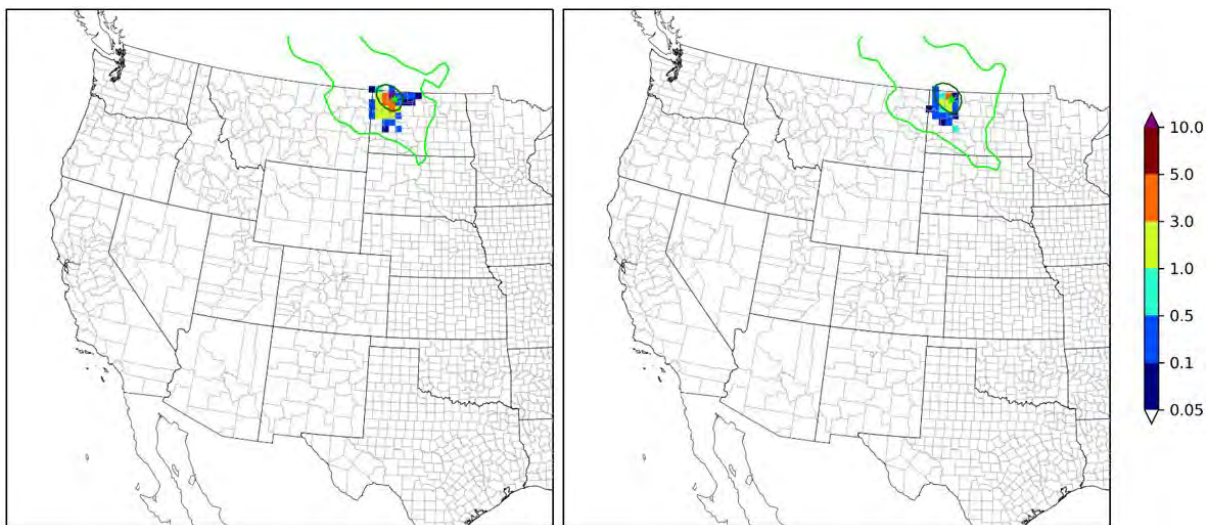

Figure 7: Oil and Gas WEP for NO_x (left) and SO_2 (right)

Figure 7 shows that no oil and gas area sources outside of the state have a significant potential to contribute to visibility impairment at Lostwood Wildlife Refuge. Emissions from North Dakota oil and gas activity are included in Section 4.3.1 of the SIP. North Dakota is monitoring the development of the oil and gas field and will address impacts from this sector in future planning periods, as needed.

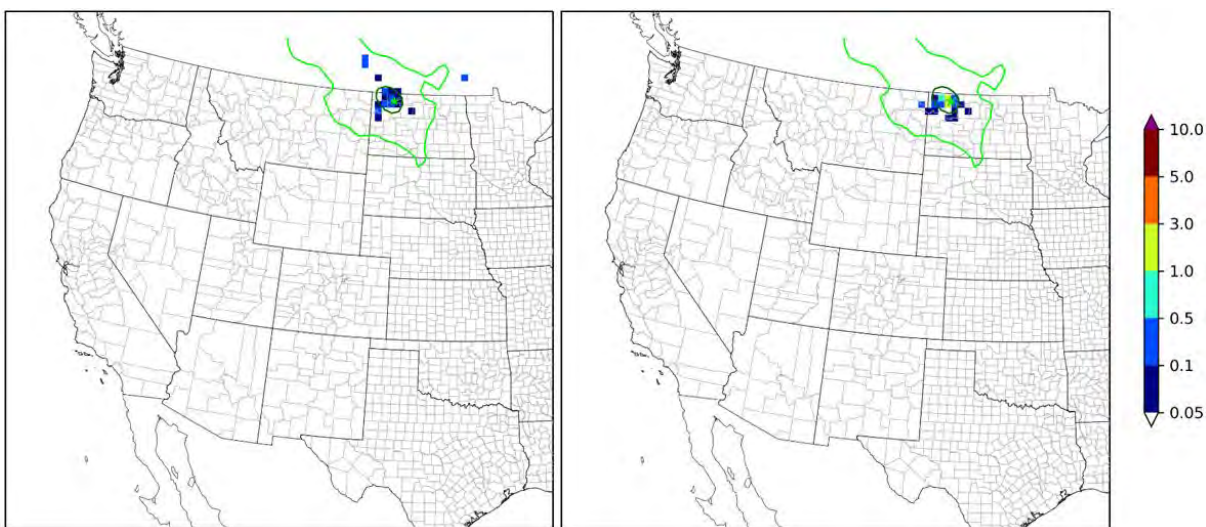

Figure 8: On-road (left) and Non-road (right) WEP for NO_x

Figure 8 shows that the contributions of the on-road and non-road sectors to impairment potentials are minimal and did not warrant review. Emissions from North Dakota non-road and on-road sectors are included in Section 4.4 and Section 4.5, respectively, in the SIP.

3 Minnesota

3.1 Voyageurs National Park

Figures 9 through 12 shows the WEP results for Voyageurs National Park. These results are also considered reflective of any potential impairment at Boundary Waters Canoe Area that emanates from North Dakota sources. This correlation was used since WEP results for Boundary Waters Canoe Area were not completed by WRAP. Additionally, Voyageurs National Park is located roughly 140 kilometers northwest of Boundary Waters Canoe Area. Therefore, Voyageurs National Park is closer to North Dakota and thus more likely to experience any potential impairment from North Dakota sources.

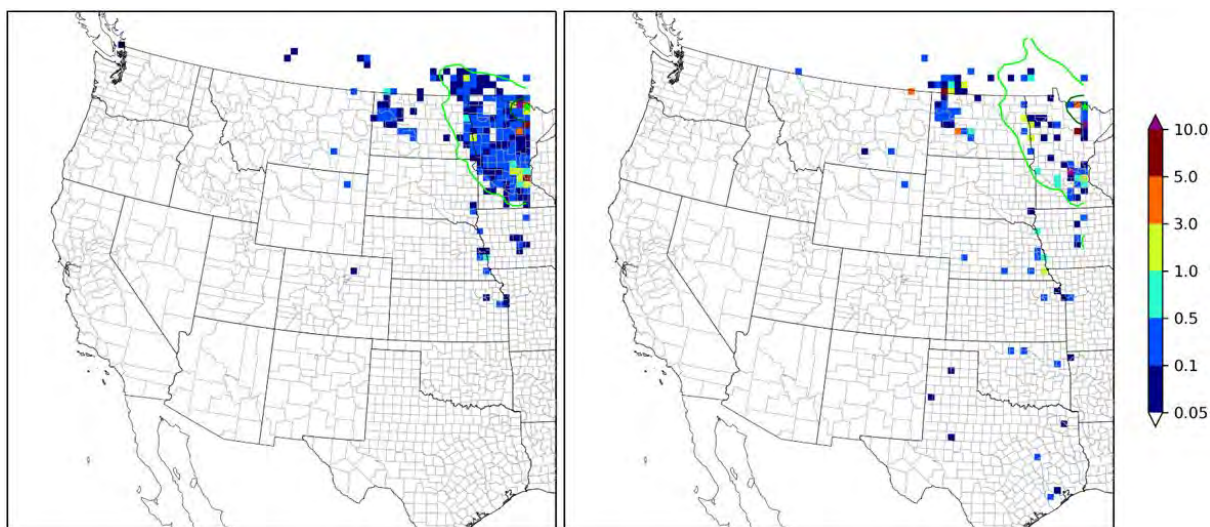

Figure 9: Total Anthropogenic WEP for NO_x (left) and SO₂ (right)

Figure 9 demonstrates that North Dakota sources have a minimal potential to impair visibility at Voyageurs National Park. The contributions along the northern border of North Dakota are Canadian contributions, which were not separated into source categories. Therefore, they are only shown in the Total Anthropogenic WEP.

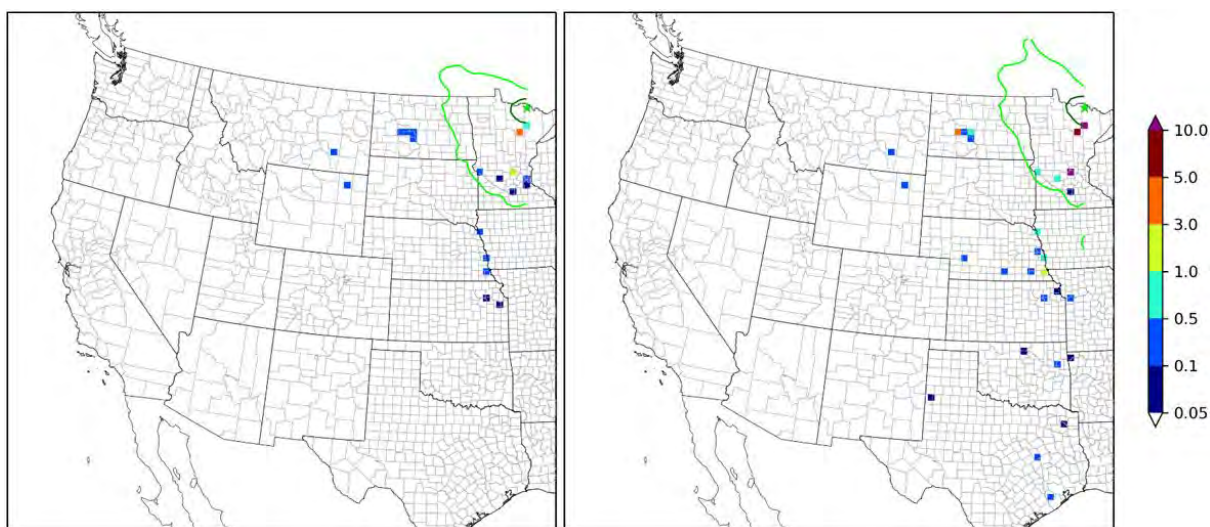

Figure 10: EGU WEP for NO_x (left) and SO_2 (right)

As stated before, Figure 10 shows that North Dakota sources have minimal contributions to impairment potentials at Voyageurs National Park. North Dakota EGU sources show some potential for impairment regarding SO_2 , justifying the Department's consideration of additional controls for reasonable progress. The four-factor analyses can be found in Section 5.2, Appendix A, and Appendix B of the SIP.

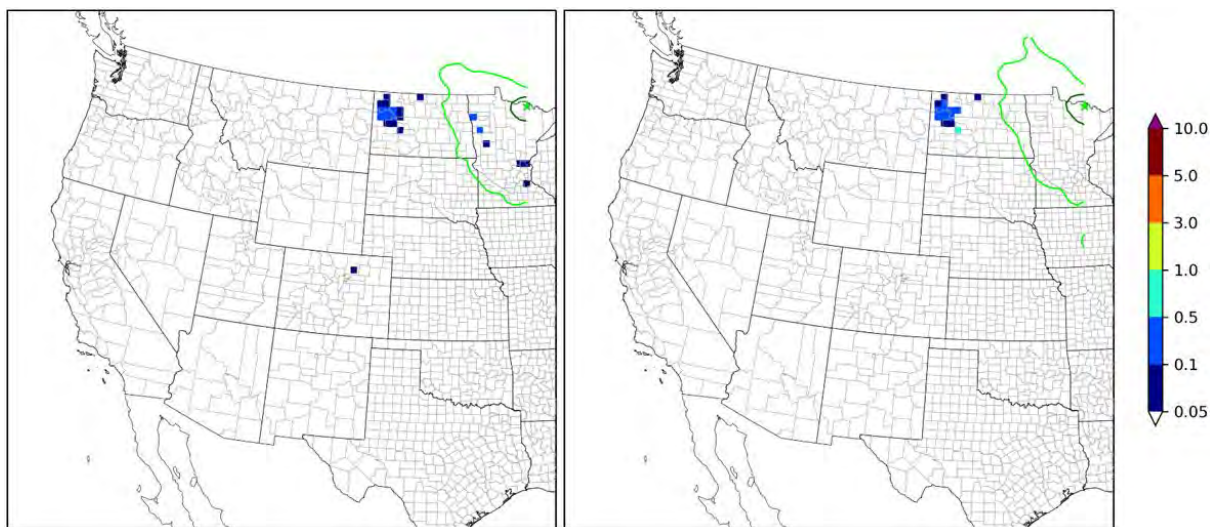

Figure 11: Oil and Gas WEP for NO_x (left) and SO_2 (right)

Figure 11 demonstrates that North Dakota oil and gas sources have a minimal impairment potential at Voyageurs National Park. Oil and gas activity is currently being monitored by the Department and is addressed in Section 5.2.11 of the SIP.

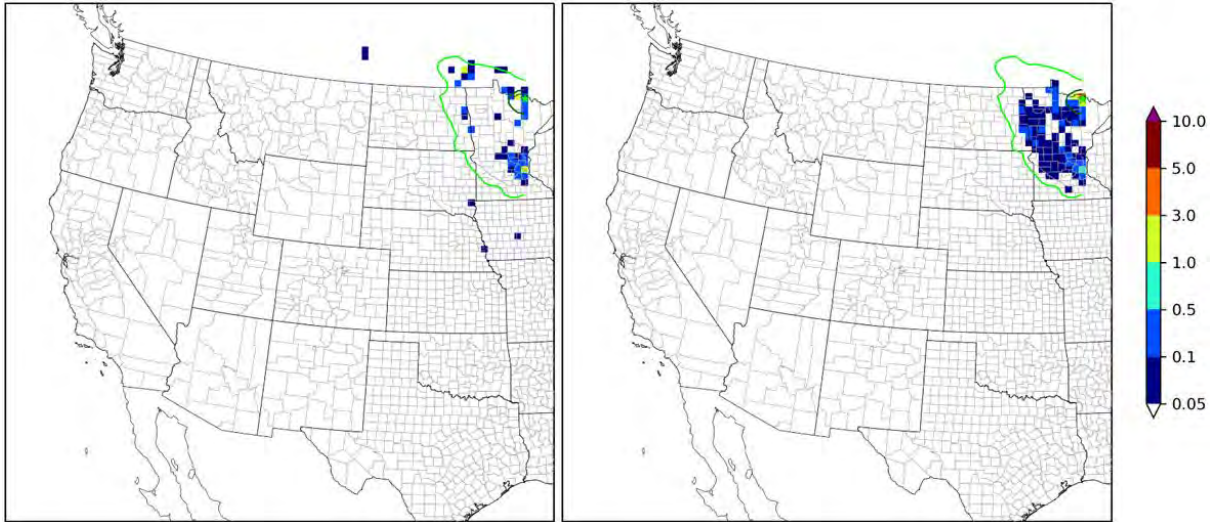

Figure 12: On-road (left) and Non-road (right) WEP for NO_x

As shown in Figure 12, much of the potential impairment from on-road and non-road sources comes from within Minnesota. On-road and non-road contributions to potential impairment at Voyageurs National Park are minimal along the North Dakota and Minnesota border and did not warrant review.

4 Montana

4.1 Medicine Lake Wilderness Area

Figures 13 through 16 shows the WEP results for Medicine Lake Wilderness Area.

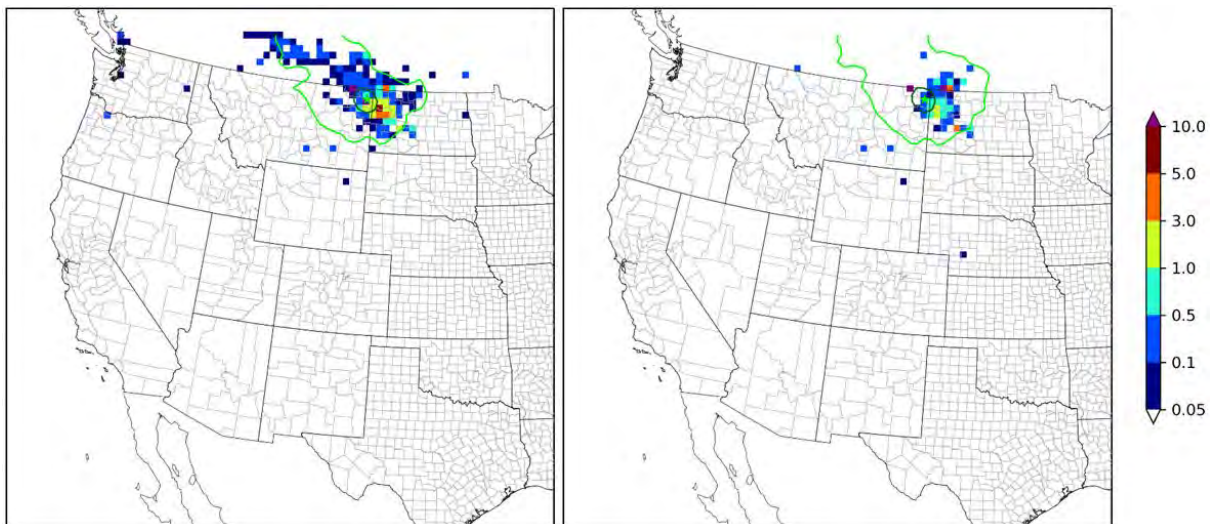

Figure 13: Total Anthropogenic WEP for NO_x (left) and SO_2 (right)

Figure 13 displays the NO_x and SO_2 WEP for total anthropogenic emissions. The following figures will demonstrate that North Dakota's contributions to impairment potential are limited to the EGU and oil

and gas sectors, justifying the Department's consideration of additional controls for reasonable progress.

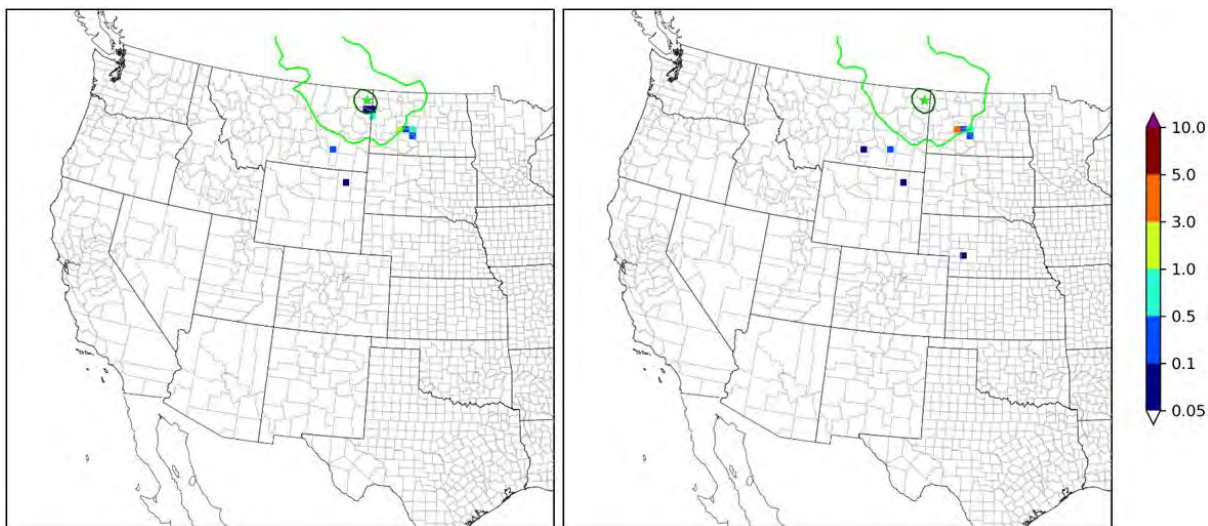

Figure 14: EGU WEP for NO_x (left) and SO₂ (right)

Figure 14 shows that North Dakota EGU sources have some potential for impairment regarding SO₂ and NO_x. This supports the Department's consideration of additional controls for reasonable progress on those sources, see SIP Section 5.2.

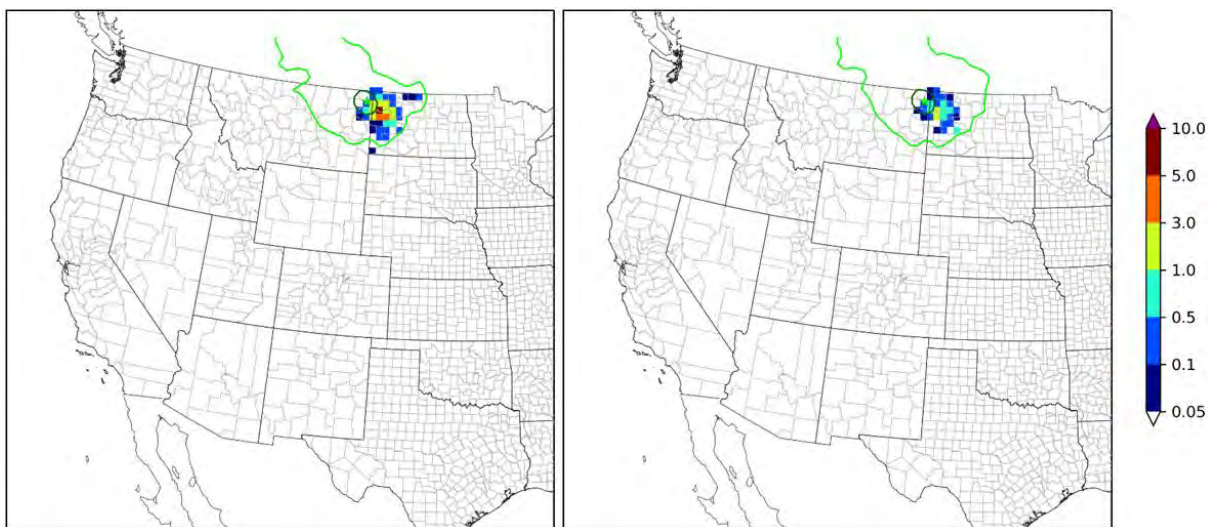

Figure 15: Oil and Gas WEP for NO_x (left) and SO₂ (right)

Figure 15 demonstrates the potential for impairment from North Dakota oil and gas sources, validating the Department's review of this activity. Oil and gas activity is currently being monitored by the Department and is addressed in Section 5.2.11 of the SIP.

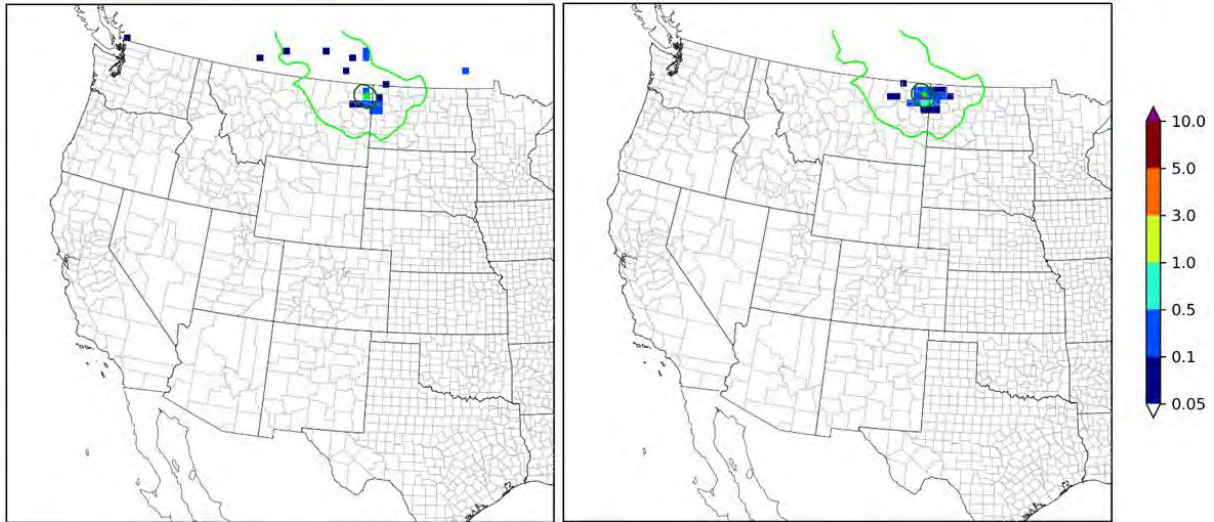

Figure 16: On-road (left) and Non-road (right) WEP for NO_x

Figure 16 indicates that the more significant potential impairment from on-road and non-road sources comes from Northeastern Montana and northwestern North Dakota. Overall, on-road and non-road contributions to potential impairment at Medicine Lake Wilderness Area are minimal and did not warrant review.

4.2 UL Bend Wilderness Area

Figures 17 through 20 shows the WEP results for UL Bend Wilderness Area.

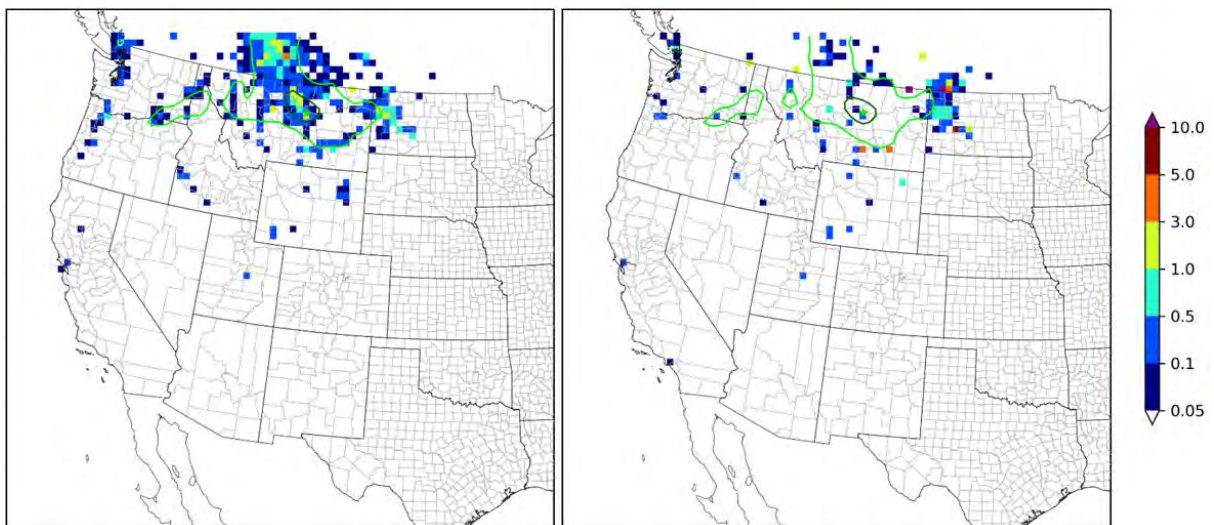

Figure 17: Total Anthropogenic WEP for NO_x (left) and SO₂ (right)

Figure 17 displays the NO_x and SO₂ WEP for total anthropogenic emissions. North Dakota contributions to the potential for impairment are minimal outside of the potential impact from EGU and oil and gas sectors.

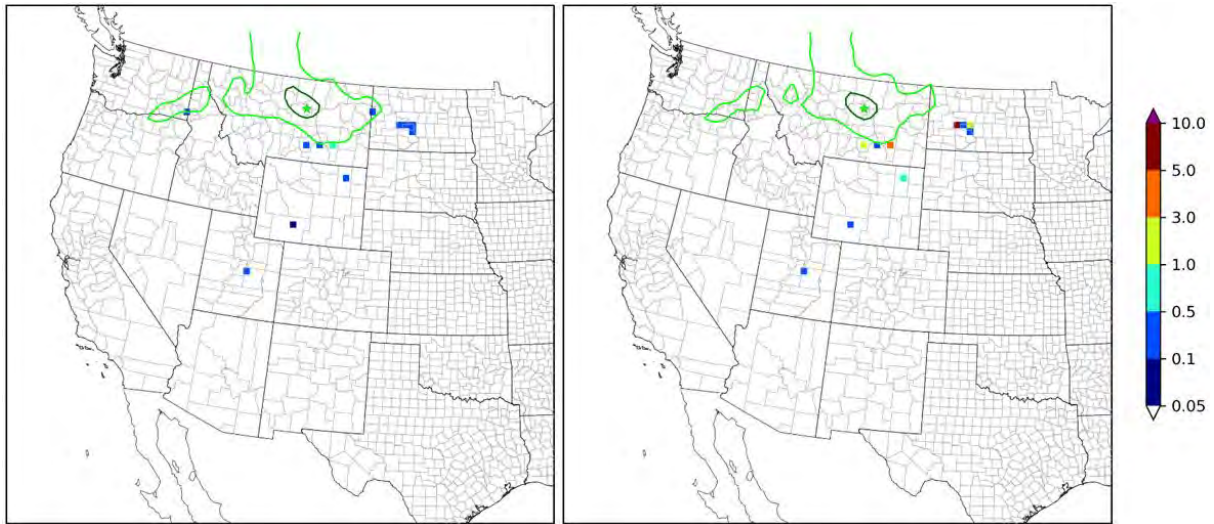

Figure 18: EGU WEP for NO_x (left) and SO₂ (right)

Figure 18 indicates that North Dakota EGU sources contribute to potential impairment regarding SO₂ at UL Bend Wilderness Area. This validates the consideration of additional controls for reasonable progress on those sources, see SIP Section 5.2.

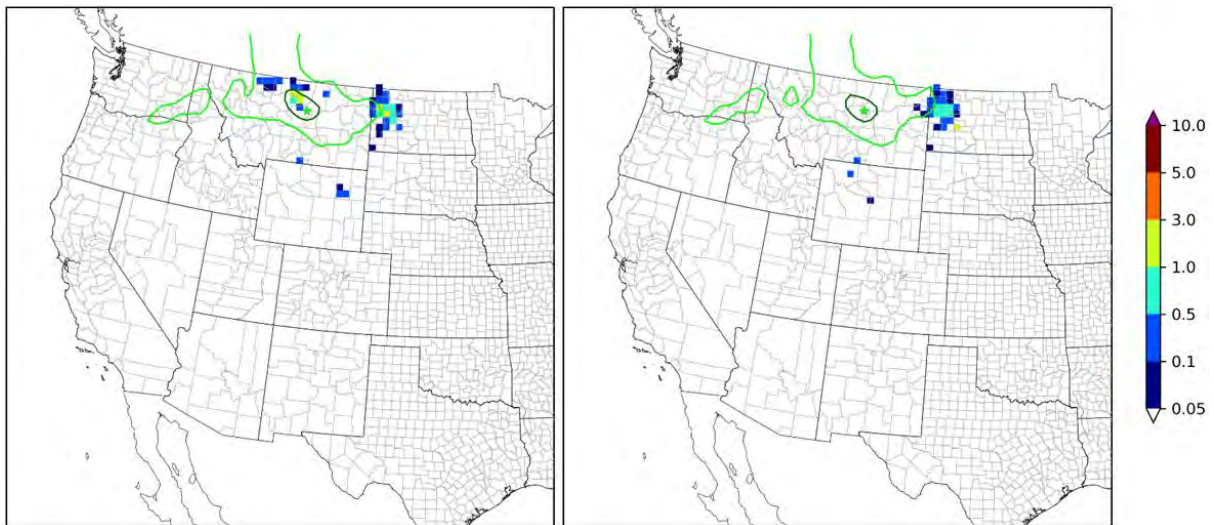

Figure 19: Oil and Gas WEP for NO_x (left) and SO₂ (right)

Figure 19 shows that North Dakota oil and gas sources have a minimal impairment potential at UL Bend Wilderness Area. Oil and gas activity is currently being monitored by the Department and is addressed in Section 5.2.11 of the SIP.

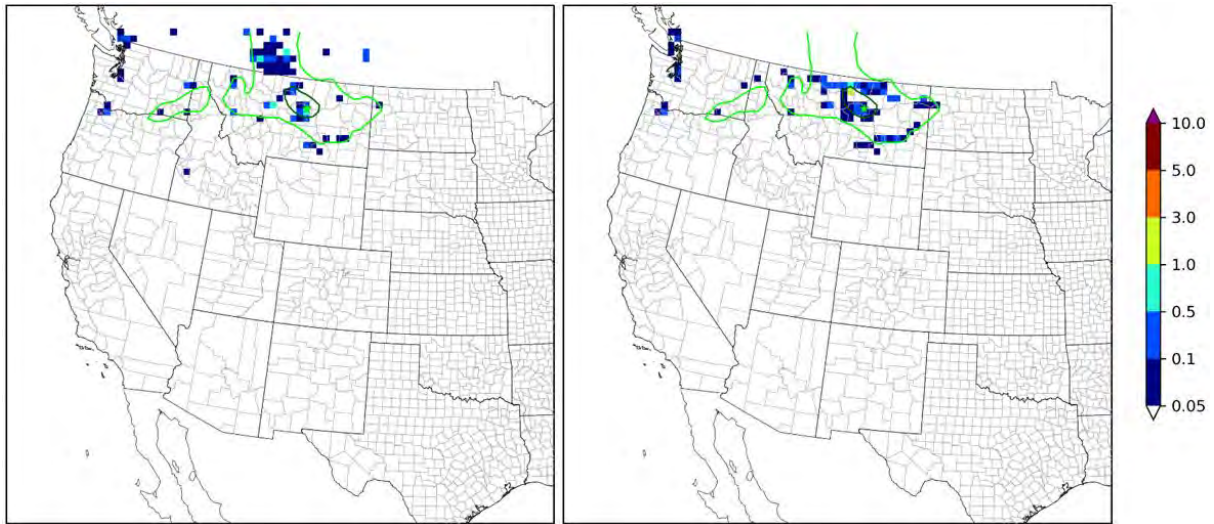

Figure 20: On-road (left) and Non-road (right) WEP for NO_x

Figure 20 indicates that the potential impairment from on-road and non-road sources at UL Bend Wilderness Area comes from within Montana. North Dakota on-road and non-road contributions to potential impairment are very minimal and did not warrant review.

5 South Dakota

5.1 Badlands National Park

Figures 21 through 24 shows the WEP results for Badlands National Park.

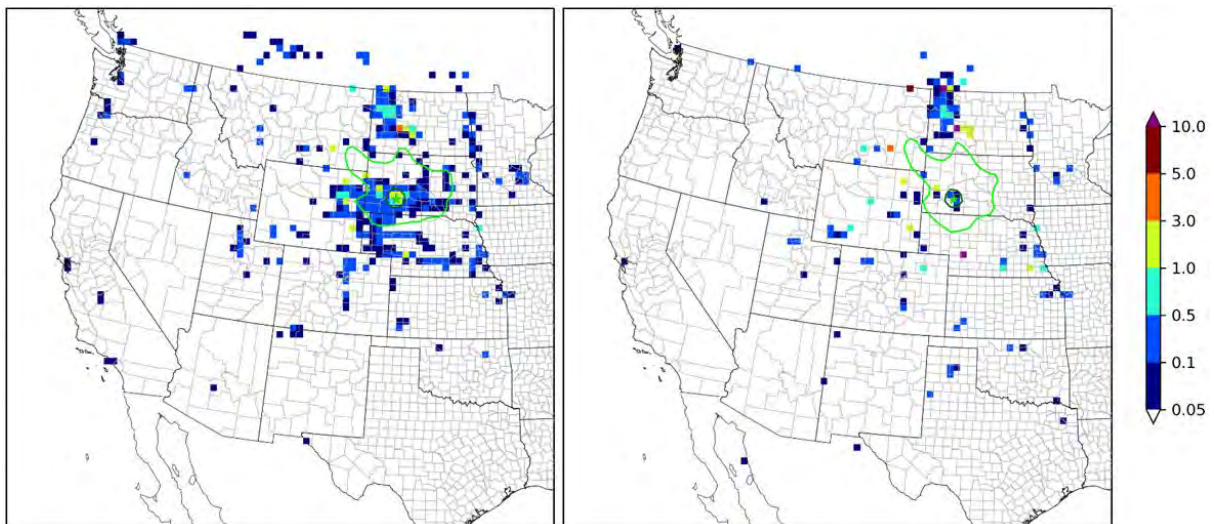

Figure 21: Total Anthropogenic WEP for NO_x (left) and SO_2 (right)

Figure 21 displays the NO_x and SO_2 WEP for total anthropogenic emissions. The following figures will demonstrate that North Dakota's contributions to impairment potential are limited to the EGU and oil

and gas sectors, justifying the Department's consideration of additional controls for reasonable progress.

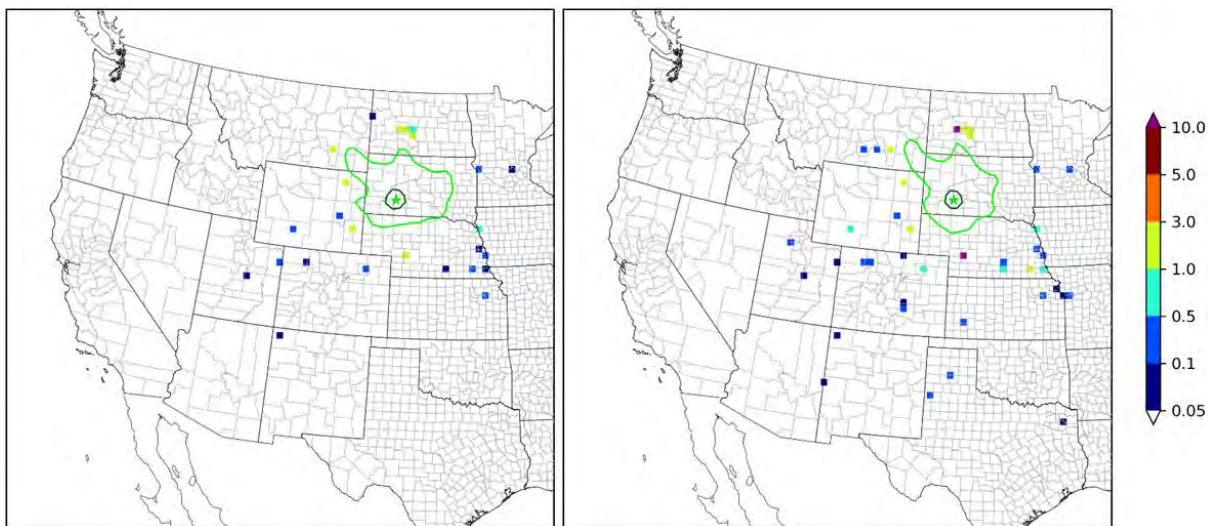

Figure 22: EGU WEP for NO_x (left) and SO_2 (right)

Figure 22 displays North Dakota EGU's impairment potential at Badlands National Park, supporting the consideration of additional controls for reasonable progress, see SIP Section 5.2.

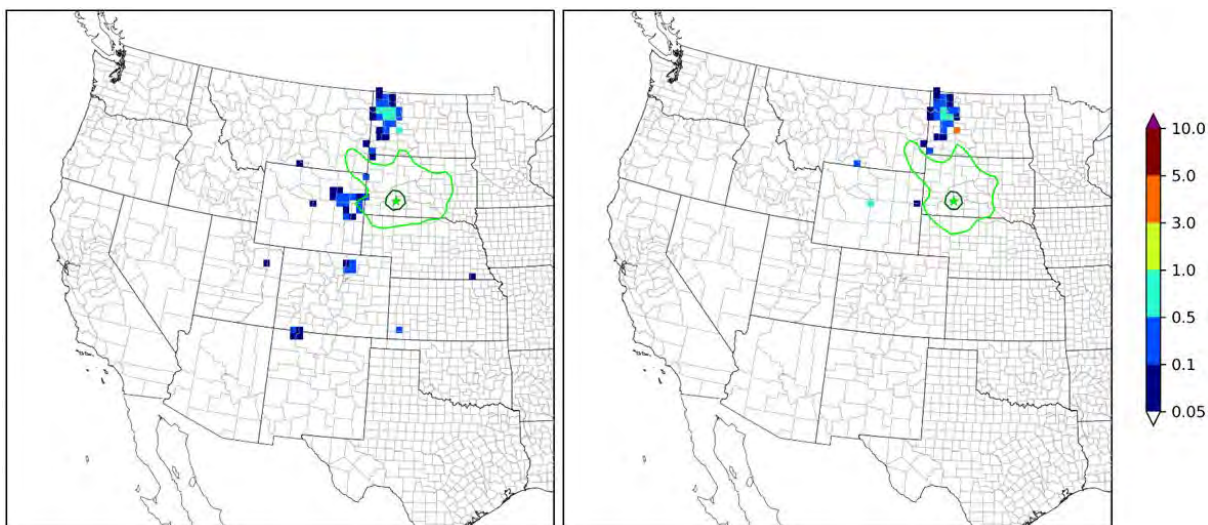

Figure 23: Oil and Gas WEP for NO_x (left) and SO_2 (right)

Figure 23 shows that North Dakota oil and gas sources have minimal impairment potential for NO_x , with some potential for SO_2 . This supports the review of this sector. Oil and gas activity is currently being monitored by the Department and is addressed in Section 5.2.11 of the SIP.

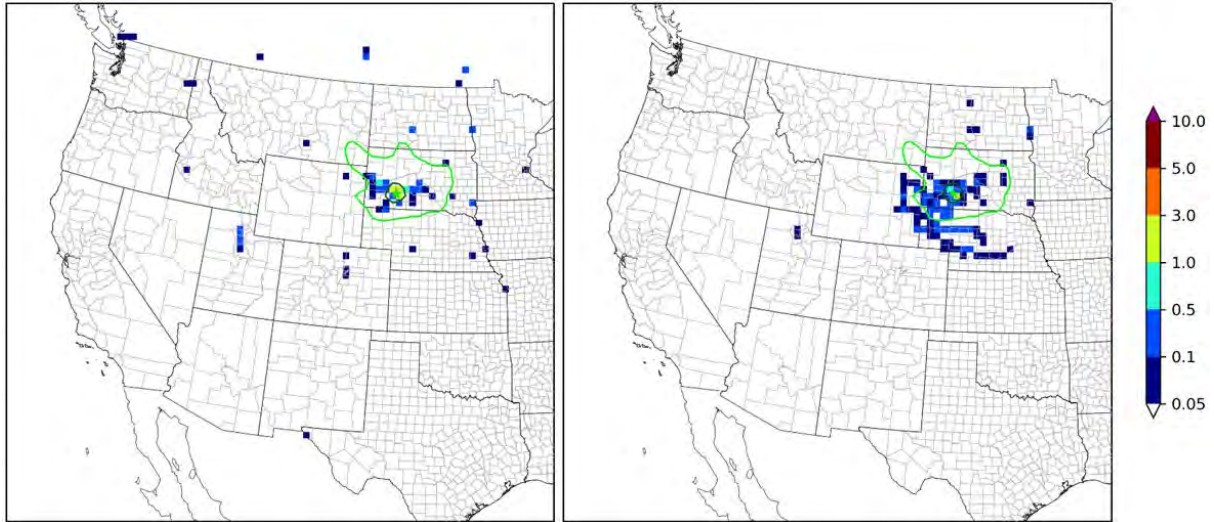

Figure 24: On-road (left) and Non-road (right) WEP for NO_x

Figure 24 indicates that the potential impairment from on-road and non-road sources at Badlands National Park largely comes from South Dakota, Wyoming and Nebraska. North Dakota on-road and non-road contributions to potential impairment at Badlands National Park are almost nonexistent and did not warrant review.

5.2 Wind Cave National Park

Figures 25 through 28 shows the WEP results for Wind Cave National Park.

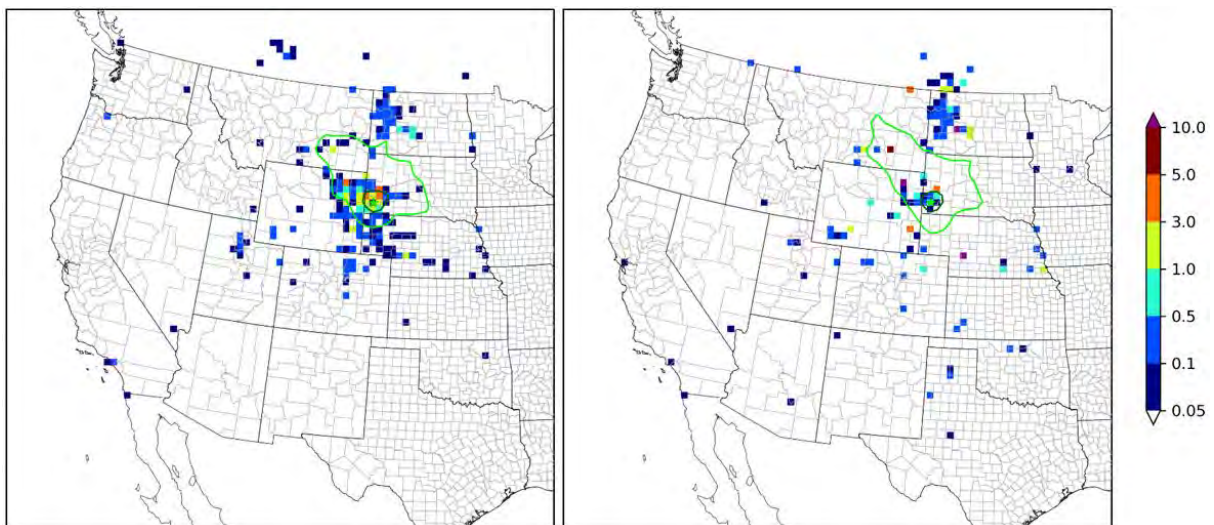

Figure 25: Total Anthropogenic WEP for NO_x (left) and SO_2 (right)

Figure 25 displays the NO_x and SO_2 WEP for total anthropogenic emissions. North Dakota contributions to the potential for impairment are minimal outside of the EGU and oil and gas sector.

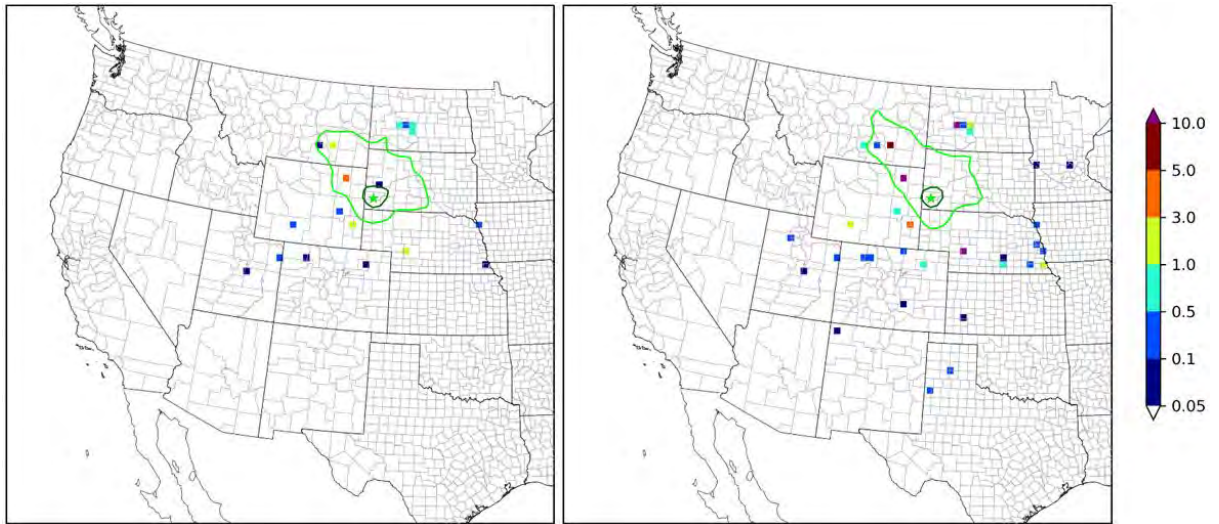

Figure 26: EGU WEP for NO_x (left) and SO_2 (right)

Figure 26 shows that North Dakota EGU sources contribute to potential impairment regarding SO_2 at Wind Cave National Park. This supports the consideration of additional controls for reasonable progress, see SIP Section 5.2.

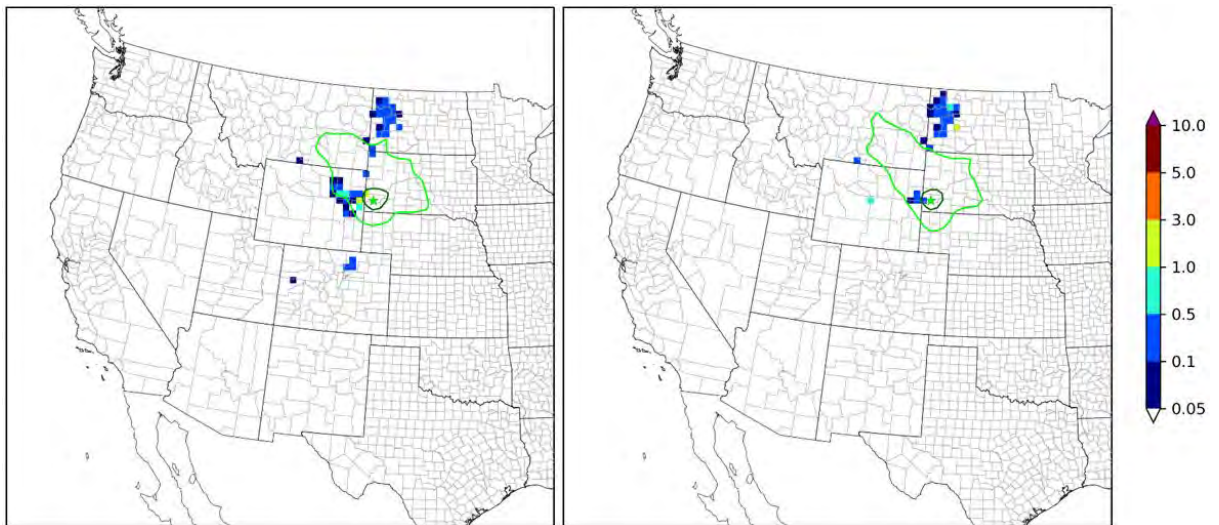

Figure 27: Oil and Gas WEP for NO_x (left) and SO_2 (right)

Figure 27 shows that North Dakota oil and gas sources have a minimal impairment potential at Wind Cave National Park. Oil and gas activity is currently being monitored by the Department and is addressed in Section 5.2.11 of the SIP.

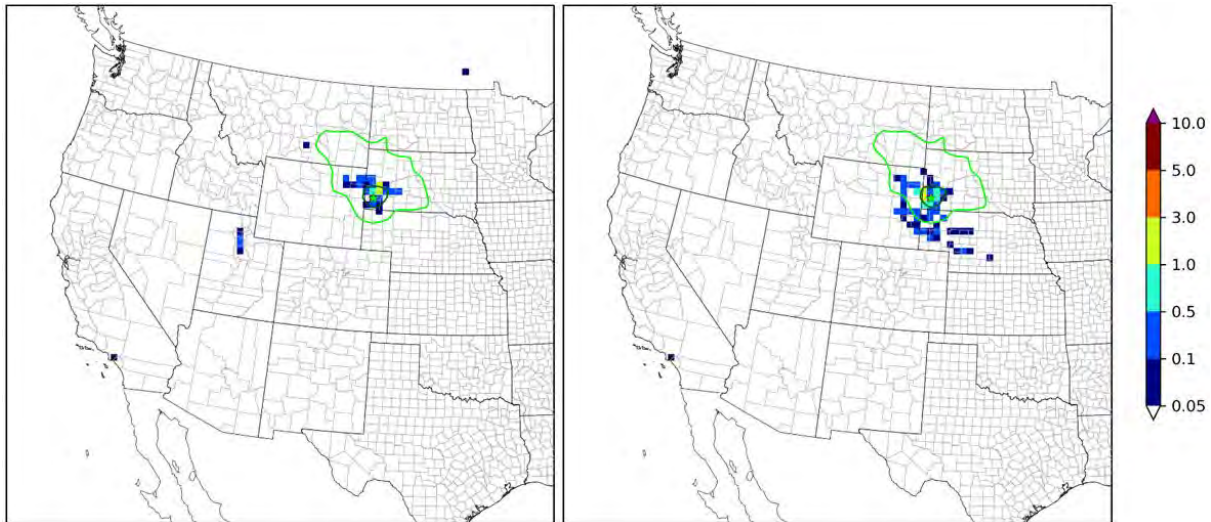

Figure 28: On-road (left) and Non-road (right) WEP for NO_x

Figure 28 indicates that the potential impairment from on-road and non-road sources at Wind Cave National Park largely comes from South Dakota, Wyoming and Nebraska. North Dakota has zero on-road and non-road contributions to potential impairment at Wind Cave National Park and did not warrant review.

6 Summary and Conclusions

The WEP analyses for Theodore Roosevelt National Park and Lostwood National Park support North Dakota's decision to evaluate the upstream oil and gas and EGU sources, as these are the major sectors that showed a potential for visibility impairment in the Class I areas. The WEP analyses also demonstrate that the potential impairment contribution from sources outside of North Dakota were minor and did not warrant further review from North Dakota during this planning period. The analyses of the nearby Montana, South Dakota, and Minnesota CIAs further support the decision to evaluate the oil and gas and EGU sources, as the potential for impairment was mostly limited to these sectors.

C.4 – WRAP Modeling Delays

February 8, 2021

To: WESTAR States and all WRAP member agencies

Re: Regional Haze modeling delays letter

Attached please find the letter from Ramboll U.S. Contracting - Environment and Health unit, detailing and explaining the reasons for delays in completing Regional Haze modeling under contract to WESTAR. The letter thoroughly describes the chronology of issues Ramboll experienced. The Regional Haze modeling effort for the 100+ Class I areas in the WESTAR-WRAP region is complex, involving a significant amount of data processing and assimilation from multiple data sources.

The modeling is largely complete at this point and Ramboll has made extra efforts to correct the cascade of problems at their expense. WESTAR-WRAP staff have been closely monitoring and sequencing the delivery of the modeling results for application in the Regional Haze SIPs and for the western regional modeling platform applications in the future. Ramboll is completing a comprehensive analysis to address western U.S. Regional Haze planning topics. As has been the case, WESTAR-WRAP staff are available to meet on the analysis and any issues with the delays.

The modeling effort has identified issues and lessons learned about the Regional Haze Rule requirements, affecting the process and timing of modeling for western U.S. Regional Haze planning:

- The delays in Summer and Fall 2019 prior to the Covid pandemic then cascaded into more delays in the 10 months from March 2020 to the present.
- To meet the Regional Haze Rule and planning guidance objectives to focus control strategies on U.S. anthropogenic emission contributions, the series of scenarios most affected by the issues in the letter (RepBase, 2028OTBa and 2002DynamicEvaluation) had to use those more computationally- and time-intensive source apportionment methods – that decision occurred in November 2019 in response to the national EPA modeling results. Those methods are necessary to separate fire and international anthropogenic emissions contributions at each Class I area for both the 2028 Reasonable Progress Goal visibility projections and to enable the “end-of-glidepath” adjustments. Those analyses now completed by Ramboll offer options for the Regional Haze SIP planners to analyze and consider in selecting Reasonable Progress Goals.
- WESTAR-WRAP members collaborated on the National Emissions Inventory Collaborative (the NEIC or “2016v1 + projections” modeling platform) at the same time the western Regional Haze modeling effort was underway. The two parallel processes certainly created some confusion and extra effort. While the NEIC data have utility in our modeling, mostly outside the WESTAR-WRAP region, for the overall required effort on Regional Haze modeling, the simultaneous projects were difficult to perfectly align, and issues emerged for individual states’ data.

Subject: Explanations for Delay in Western States Regional Haze Modeling

Dear Mary:

This letter documents and provides reasons for delays in the chronology of Ramboll's completion and delivery of the Regional Haze (RH) photochemical modeling results since late 2018, for the western states on the WRAP Technical Support System (TSS). The TSS is our delivery target since western states and other WRAP partners use it for Round 2 RH State Implementation Plans (SIPs) due July 2021. This work for WESTAR-WRAP has been done mainly under WESTAR Contract 19-01. First and foremost, I want to emphasize how much we value WESTAR-WRAP membership and the western states in particular as important clients and these delays in no way indicate a lack of commitment by Ramboll or us not placing this work as highest priority. This is the most important project that I and my staff have right now, and we are trying to finish delivery of high quality RH technical work products as quickly as we can.

The WRAP western state RH CAMx source apportionment is quite complex and complicated integrating numerous sources of data (e.g., 2014NEI, WRAP states data, EPA 2016v1 platform, natural and international emissions, data products of WRAP workgroups and projects etc.), because the vast majority of emissions affecting RH planning are out of the control of the states, but must be thoroughly assessed with photochemical modeling per EPA RH planning guidance. The work tasks in Contract 19-01 involved a lot of moving parts and pieces of data that needed to be properly implemented presenting multiple opportunities for mistakes. However, that is not an excuse as Ramboll has a reputation and track record on performing such complicated and high-quality air quality modeling studies.

In my over 40 years as an air quality consultant, I have never had a project that had so many setbacks for so many different reasons. Ramboll is not blameless in this as some delays are our fault and we have taken a financial penalty by all the re-running of modeling scenarios, not to mention the emotional and stressful aspects of these delays. But many of the delays have been unique and due to unforeseen circumstances that were out of our control, including:

- Federal government shut-down in December 2018 and January 2019 delayed getting EPA's 2014 modeling platform at the outset of the project.

- EPA's 2014 GEOS-Chem simulation that we planned to use for Boundary Conditions (BCs) was flawed with June & July SO₂/SO₄ overestimation and year-round ozone overestimation. As a result, we had to conduct our own unplanned 2014 GEOS-Chem simulation to correct it that took several months.
- Delays and data processing decisions at EPA in releasing the National Emissions Inventory Collaborative (NEIC) 2016v1 modeling platform and 2023 and 2028 future year emission projections caused delays in getting future year emissions, as well as errors in the data, as noted below.
- Ramboll modeling computer servers for this work are located in northern California. The Pacific Gas & Electric utility instituted Public Service Power Shutoffs (PSPS) to prevent wildfires that shut down the power to the computers doing the modeling during portions of September-October 2019.
- In November 2019, California Air Resources Board discovered errors in the 2014v2/RepBase fugitive dust emissions they provided that caused delays while we re-processed the emissions and re-ran model simulations.
- COVID-19 Shelter-in-place from March 2020 to the present disrupted and slowed down the modeling. It took a while to figure out how to work effectively remotely. Also with no one in the office, when a computer goes down, hangs or there is a need to mount a new disk to make disk space, there are longer delays than normal as someone has to make a trip to the office.
- In June 2020 we found that some anthropogenic state-controllable sources for RH planning were both incorrect and/or double-counted in the NEIC 2016v1 modeling platform data, in both of the key scenarios for RH planning, the already-completed RepBase and 2028OTBa projection scenarios in the WESTAR-WRAP modeling effort, that caused a 3-month delay (Jun-Jul-Aug 2020). The emissions had to be reviewed by Ramboll and the states for corrections, updated and fixed and SMOKE emissions modeling of re-done so new RepBase2 and 2028OTBa2 could be done.
- Because of the problems and reprocessing required for the NEIC 2016v1 and 2028 emissions, technical decisions were made by WESTAR-WRAP members in RH work groups, to change some of the emissions sector datasets to be used in the new RepBase2 and 2028OTBa2 scenarios from what was in Ramboll's contract necessitating re-processing and some additional delays. The effect of these decisions was non-zero in terms of Ramboll effort, but were timely and improved the representativeness of the RepBase2 and 2028OTBa2 modeling results for RH planning.
- Unprecedented wildfires in Northern California August through November 2020 interfered with staff working as PM_{2.5} concentrations in excess of 200 µg/m³ blanketed the region making going outdoors and travel dangerous. Many staff were on-call prepared for evacuation and worked much less efficiently under stressful conditions.
- Coding errors in the Ramboll CAMx model caused two re-runs of the CAMx RepBase2 and 2028OTBa2 source apportionment simulations in late 2020. As these runs take ~28 days to run, each re-run can cause a 1-2 month delay as we have to debug what the error is, fix it and re-run.

Ramboll was originally teamed with a Subcontractor whose role was to do most of the SMOKE emissions modeling. The same Subcontractor had a similar role when Ramboll developed the WRAP WestJumpAQMS 2008 and IWDW-WAQS 2011 modeling platforms and performed well.

Attachment 1 has a chronology of events that occurred and caused delays in delivering products on schedule. Below we discuss how some of these specific events delayed some of the key project deliverables.

- The schedule for the first big deliverable was WRAP-WAQS Shake-Out 2014v1 CMAQ and CAMx platforms, model evaluation and Close-Out meeting by March 2019. The Close-Out meeting occurred in April 2019 and delivery of the 2014v1 platform to IWDW in May. The causes for these delays are as follows:
 - Initial contract award was received December 11, 2018, affecting the proposed schedule from Ramboll. If we have started December 1, 2018 as originally planned we likely would have noticed the missing files for EPA's 2014 platform on their ftp site before the unexpected government shut-down.
 - Federal government shut-down December 22, 2018 through January 25, 2019 that delayed getting the EPA 2014 modeling platform by over a month as the EPA ftp site did not include all of the files and EPA staff were unavailable to provide them.
 - In February 2019 we found that the EPA 2014 GEOS-Chem had overestimation issues and in March 2019 EPA re-ran June and July to fix one of the problems so that final 2014v1 CMAQ/CAMx simulations, MPE and database transfer were delayed from the March target timeframe until April-May 2019.
- The next big deliverables, as identified in the May 29, 2019 WESTAR 19-01 Amendment#2 (A2), was 2014v2 emissions modeling, 2014 GEOS-Chem modeling and 2014v2 CMAQ/CAMx modeling to be completed by July 2019 and Representative Baseline (RepBase) modeling to be completed by August 2019. In reality, the first CAMx 2014v2 simulation was not completed until September 2019 and a series of emission updates were made so that the final 2014v2 CAMx base case was not completed until early December 2019. The first RepBase run was not completed until January 2020. The reasons for the delays of the final 2014v2 and initial RepBase simulations are as follows:
 - The July 2019 deadline for the 2014v2 platform was probably overly ambitious, but August should have been doable.
 - A key update in the 2014v2 platform was 2014 emissions for California that CARB provided to the SMOKE emissions Subcontractor in May 2019. In July the Subcontractor started asking questions and needing updates to the 2014 California inventory, so it appears they sat on and didn't look at the data for two months. 2014v2 SMOKE emissions processing was delayed as the Subcontractor's SMOKE modeler had many trips, such as to Korea (June), South America (July) and the EPA Emissions Inventory Conference in Dallas (August). Ramboll finally received the disk drive with the 2014v2 emissions on August 29, 2019. Note that Ramboll has worked very well with this Subcontractor in past studies (e.g., 2008 and 2011 platforms), but personnel

changes appear to have affected their ability to deliver in a timely fashion. Ramboll ultimately took over the SMOKE emissions modeling so that it could be performed in a more timely manner.

- Ramboll's initial CAMx 2014v2 simulation in September 2019 produced high ozone in northeast Wyoming that was traced to an emissions modeling error that allocated all the annual average O&G emissions to January in some counties.
- The Subcontractor corrected the 2014v2 O&G emissions and a revised CAMx 2014v2 simulation was conducted in October 2019.
- The California Air Resources Board informed us in November 2019 that there were errors in California's 2014v2/RepBase fugitive dust emissions and sent corrections that were incorporated into the RepBase emissions delaying the RepBase CAMx simulation until January 2020.
- Also in November 2019, we discovered errors in the RepBase fire emissions files provided by the WRAP Fire & Smoke Work Group (FSWG) contractor that produced negative PM_{2.5} emissions that had to be corrected by the FSWG contractor. Identification of these sort of issues for fire and many other source categories is a common and required task for assembly of air quality modeling scenarios in a platform. The evaluation and correction of the fire emissions files was another delay in the sequence to assemble RepBase.
- Errors in EPA's proprietary and lightly documented AMET MPE Tool that EPA did not fix until January 2020 (and only EPA can fix), that we use to calculate performance statistics to be in compliance with EPA modeling guidance, meant that some of the model performance evaluation (MPE) products for the 2014v2 simulations were delayed.
- WESTAR Contract 19-01 Amendment#5 (A5) dated November 22, 2019 had several deliverables with the key ones as follows: (1) 2002 Dynamic Evaluation (2002DE) CAMx simulation completed by February 2020; (2) 2028OTB CAMx done by February 2020; and (3) CAMx 2028 source apportionment done by March 2020. There were numerous iterations in these simulations so that they were not finally completed until January 2021 for the following reasons:
 - After these milestones were set in the contract and in discussion with Regional Technical Operations Work Group Co-Chairs and WESTAR-WRAP staff and to meet objectives (e.g., obtain separate fire and U.S. anthropogenic emission contributions), the RepBase, 2028OTBa and 2002DE were turned into source apportionment simulations each of which takes ~28 days to run. Thus, the original schedule in A5 as the awarded contract required was physically impossible to meet given the changes in the run times from a CAMx standard model run (~5 days) to a source apportionment run (~28 days).
 - The delays in the 2014v2 and RepBase simulations meant that A5 modeling could not start until January 2020 instead of November 2019 as originally envisioned. This meant that the 2028OTB emissions and first CAMx 2028OTB simulations and visibility projections were completed in March-April instead of February 2020.

- In March 2020, shelter-in-place orders were mandated due to the COVID-19 pandemic that caused a slow-down in the modeling for several reasons:
 - People had to move their work stations from the office to home where they do not have as efficient a work space (e.g., copier machines, access to computers, etc.).
 - It took some time for people to figure out how to work from home effectively and efficiencies suffered.
 - Schools and day cares closed so parents had full time responsibility for their children and had to assist teaching from home.
 - When the high performance Linux computers in the office went down, hung or we needed to mount disks for backups to make more disk space, someone had to physically come in to the office and there were restrictions on how that could be done.
- The 2002 Dynamic Evaluation emissions development to backcast 2014 emissions to 2002 turned out to be a much bigger task than originally scoped by Ramboll and as awarded in the contract. It was deemed less critical than the 2028OTB modeling so was de-emphasized compared to getting the 2028 visibility projections done.
- How to treat fires in the 2028 MID projections caused some delays as there were modeled fires on some days in the IMPROVE MID; MID are selected in part to limit fire contributions.
- Double-counted and/or incorrect anthropogenic state-controllable sources for RH planning were discovered in the NEIC 2016v1 modeling platform due in part to EPA emissions processing of the 2016v1 files having O&G sources in the Non-EGU Point files instead of in the O&G files. Several WESTAR-WRAP region states also identified incorrect emissions rates in the 2016v1 files. This caused a series of state-by-state review and correction actions and a 3-4 month delay at a critical point in the regional haze modeling. This was probably the single biggest issue that caused delays in the project and required the following corrective action:
 - Ramboll conducts intensive review of the EPA 2016v1 platform emissions to identify the problems.
 - Western states review and update their RepBase and 2028OTBa emissions to now be RepBase2 and 2028OTBa2 inputs.
 - The WESTAR-WRAP project manager decides not to continue to use the NEIC 2028 projections for some source sectors (e.g., WRAP non-EGU Point), in response to requests from the WESTAR-WRAP region states, in 2028OTBa2 modeling and use 2014 instead.
 - Ramboll creates harmonized emission inventories for RepBase2 and 2028OTBa2 and conducts SMOKE modeling.
 - Re-run RepBase2 and 2028OTBa2 source apportionment simulations.

- WESTAR Contract 19-01 Amendment#10 (A10) provided funding for updating the RepBase2 and 2028OTBa2 emissions to address the EPA double counting issue and had a detailed schedule: (1) CAMx RepBase2 H-L SA run done by Nov 17, 2020; (2) CAMx 2028OTBa2 H-L SA run done by Nov 28, 2020; (3) CAMx 2028OTBa2 L-L SA run done by Dec 30, 2020. In reality, the final RepBase2 and 2028OTBa2 H-L SA runs were not done until January 2021 due to multiple re-runs:
 - The RepBase2 and 2028OTBa2 H-L SA simulations take approximately 28 days to run. The first RepBase2 and 2028OTBa2 H-L SA runs were completed within the A10 schedule (Nov 2020), but a series of issues were discovered that caused re-runs as follows:
 - The way lightning NOx emissions were treated was changed from millions of virtual point sources to a netCDF 3-D input to be more computationally efficient. However, a coding error in the CAMx v7.0 model caused the netCDF 3-D inputs not to work correctly and it adversely affected the source apportionment results necessitating going back to the virtual point source input approach.
 - The second round of RepBase2 H-L SA runs was performed in December 2020, but was invalid due to missing New Mexico Non-EGU Point emissions (Ramboll's fault).
 - A third set of RepBase2 and 2028OTBa2 simulations were conducted the end of December 2020 into January 2021 and another coding error was discovered in CAMx v7.0 that dropped point source SO2 emissions.
 - The fourth set of RepBase2 and 2028OTBa2 H-L SA simulations finished in late January 2021 and were post-processed and transferred to the TSS by end of January.

I hope you find this letter useful in helping to explain why the regional haze modeling for the WESTAR-WRAP region is delayed. I believe these issues are behind us and the regional haze modeling results are now being populated onto the WRAP TSS. I do not foresee any remaining modeling or data delivery issues for the remaining tasks over the next 2-3 months, and Ramboll is closely coordinating with WESTAR-WRAP staff and the RTOWG Co-Chairs.

If you need more information or want me to personally talk to EPA or any of the States with WESTAR-WRAP staff in attendance, please let me know as I am always available and always try to live up to my commitments and responsibilities.

Best Regards,

Attachment 1. Timeline of events that caused delays in the WRAP western states regional haze modeling.

Approximate Date	Event
Dec 11, 2018	Initial WESTAR Contract 18-12 to development 2014 Shake-Out platform was received 10 days after project start date (Dec 1, 2018)
Dec 2018-Jan 2019	Federal government shut-down Dec 22, 2018 – Jan 25, 2019 caused over a month plus delay in getting all files from EPA's 2014 modeling platform as the 2014 platform files on the EPA ftp site were incomplete.
Feb 2019	Found that EPA's 2014 GEOS-Chem run that was planned to be used for BCs was flawed as it had too high SO ₂ /SO ₄ in Jun & Jul and overstated O ₃ year-round. This meant Ramboll had to perform an unplanned 2014 GEOS-Chem run that took several months to complete.
Mar 2019	EPA re-runs GEOS-Chem for Jun & Jul without volcano eruption fixing Jun & Jul SO ₂ /SO ₄ overestimation problem in BCs but causing delays in delivering the 2014v1 Shake-Out modeling platform in March 2019.
Jun – Aug 2019	2014v2 SMOKE emissions modeling delayed 3 months due to unavailability of Subcontractors SMOKE modeler.
Sep 2019	Corrections needed for error in SMOKE emissions modeling of 2014v2 (overstates Wyoming Jan O&G emissions) caused another month delay.
Sep – Oct 2019	PG&E Public Service Power Shutoffs (PSPS) cut-off power to Ramboll's Linux computers in their Novato, CA office shutting down progress on 2014v2, RepBase2 and 2028OTB modeling.
Nov 2019	California Air Resources Board informs us that California Fugitive Dust emissions are in error in 2014v2/RepBase and sends update that caused delays.
Nov 2019	The RepBase fires from the FSWG have errors that produce negative PM _{2.5} emission that need to be fixed
Dec 2019	EPA's AMET MPE tool does not work right and does not generate all the MPE products that are needed. EPA AMET contact goes on holiday and issue is not fixed until after they come back in Jan 2020.
Jan 2020	Modeling for 2028OTB and 2002DE that was supposed to start in November 2019 started in Jan 2020 instead due to delays and finishing up 2014v2 and RepBase modeling.
Mar 2020 - present	COVID-19 shelter-in-place disrupts modeling as people can no longer go to the office and must work from home. That reduces efficiency and modeling takes longer due to more computer down time.
Apr – May 2020	Extra time to determine how to treat modeled fires in visibility projections for the MID that are not supposed to have any episodic fire.
Jun – Sep 2020	Double counted sources in EPA's 2016v1 modeling platform caused a stop of the modeling and have Ramboll and the states re-work the emissions, fix them and redo the SMOKE modeling causing a 3-4 month delay.
Jun – Sep 2020	Given problems with EPA 2016v1 platform 2028 emission projections, WRAP decides to change what emissions are being used in 2028OTB emission scenarios from what was in Ramboll's contract.
Aug – Nov 2020	Massive wildfires in California caused extremely high PM _{2.5} concentrations, limited travel in the region and caused inefficiencies in work.
Nov 2020	RepBase2 and 2028OTBa2 H-L SA runs have to be re-done due to coding error in CAMx v7.0 treatment of netCDF 3-D lightning NO _x inputs.
Dec 2020	Second RepBase2 H-L SA run has to be re-done due to missing New Mexico non-EGU point source emissions.
Dec 2020 – Jan 2021	Third RepBase2 and 2028OTBa2 H-L SA runs have to be re-done due to coding error in source apportionment species mappings that dropped point source SO ₂ emissions.
Jan 2021	Fourth RepBase2 and 2028OTBa2 H-L SA runs have satisfied all the QA checks and appear correct so that 2028 visibility projections and other data will be transferred to the WRAP TSS by the end of January 2021.

1.0 Purpose:

The Western Regional Air Partnership and Western Air Quality Study (WRAP-WAQS) [2014 Regional Haze modeling platform](#) is the latest of a series of regional modeling efforts supporting western U.S. air quality planning and management. The WRAP technical analyses follow the Environmental Protection Agency's (EPA) [Modeling Guidance for Demonstrating Air Quality Goals for Ozone, PM2.5, and Regional Haze](#) (November 2018) and the [Technical Support Document for EPA's updated 2028 regional haze modeling](#) (September 2019). The analyses fulfill the objectives of the [WRAP 2018-2019 Workplan](#) as updated and approved by the WRAP Board on April 3, 2019 and have been collectively designed, implemented, and reviewed by the [WRAP Technical Steering Committee](#) and its workgroups and subcommittees.

[The Western Regional Air Partnership \(WRAP\) Technical Support System](#) (TSS) hosts the visibility monitoring, emissions, and air quality modeling analyses that support the 15 western states in developing regional haze state implementation plans (SIPs). This reference document describes the WRAP emissions and modeling analyses and illustrates how the TSS products can be applied and interpreted to support the 2028 visibility progress demonstrations for western U.S. Class I areas.

2.0 Background:

The Regional Haze Rule requires states to demonstrate progress every ten years toward the Clean Air Act goal of no manmade visibility impairment. [EPA guidance for tracking visibility progress](#) (December 2018) defines a visibility impairment tracking metric (measured in deciview) using observations from the Interagency Monitoring of Protected Visual Environments ([IMPROVE](#)) [monitoring network](#) sites that represent Class I areas. EPA defined in the Regional Haze Rule and guidance a Uniform Rate of Progress glidepath for the 20% most impaired days as the straight line from the 2000-2004 IMPROVE 5-year average baseline to EPA estimates of future natural visibility conditions, plotted at 2064. In the first regional haze planning period, 2000-2018, EPA guidance interpreted most impaired days as those days with highest total haze. States were required to demonstrate visibility progress by 2018 compared to the Uniform Rate of Progress glidepath for the haziest days and no degradation of visibility on the clearest days from the 2000-2004 IMPROVE 5-year average baseline. Visibility on the clearest days improved between 2000 and 2018 across the Class I areas in the western U.S. However, smoke from wildfire and wildland prescribed fire events and dust events on the haziest days made tracking the visibility benefits due to reducing U.S. anthropogenic emissions more difficult.

For the second regional haze implementation period, 2018-2028, states are required to demonstrate visibility progress by 2028 for the most impaired days and no visibility degradation for the clearest days. [EPA guidance](#) (December 2018) defined most impaired days as those days with the highest fractional contribution to aerosol light extinction from anthropogenic sources. EPA statistical methods use IMPROVE measurements of carbon and crustal materials to separate contributions from episodic extreme natural events (e.g., wildfire or dust) from routine natural and anthropogenic contributions. Ammonium sulfate and ammonium nitrate are assigned primarily to anthropogenic emissions with smaller contributions from routine natural sources. This statistical approach does not separate contributions due to U.S. anthropogenic emissions from those of international anthropogenic emissions. Since states do not have authority to reduce international emissions, WRAP conducted source apportionment modeling analyses to evaluate U.S. anthropogenic contributions to haze and progress in reducing U.S. anthropogenic contributions to haze over time.

Table 1 summarizes the emissions and modeling scenarios, source apportionment runs, and alternative visibility progress analyses that were performed to support state regional haze planning.

**Table 1. WESTAR-WRAP Emissions and Modeling Scenarios – update of January 18, 2021

*** controls adopted by states in SIPs, this scenario is likely not possible until 2021 (*unfunded at present, not in Workplan*)

**** fire not paired in space or time with 2014 or RepFire activity, these sensitivity scenarios could give potential future wildfire contribution relative to 2028OTBa2

***** fire is paired in space and time with RepFire activity; this sensitivity scenario gives potential future Wildland Prescribed fire contribution relative to 2028OTBa2

*****Dynamic Evaluation compare US anthropogenic contributions for 2002 Hindcast, RepBase2, and 2028OTBa2 to demonstrate alternative rate of visibility improvement

3.0 Emissions Scenarios:

The WRAP 2014v2 inventory was based on the [2014v2 National Emissions Inventory](#) (NEI) plus [updates provided by western states](#) through WRAP Regional Haze workgroup's [Emissions and Modeling Protocol subcommittee](#).

Table 2 defines the emissions data sources used for the WRAP 2014v2, Representative Baseline (RepBase2), and 2028 On the Books (2028OTBa2) emissions scenarios. Sector-specific data sources and assumptions are discussed in the companion [TSS Emissions References](#) document (September 2021). Future fire emissions sensitivities and 2002 hindcast emissions are also detailed in the [TSS Emissions References](#) document.

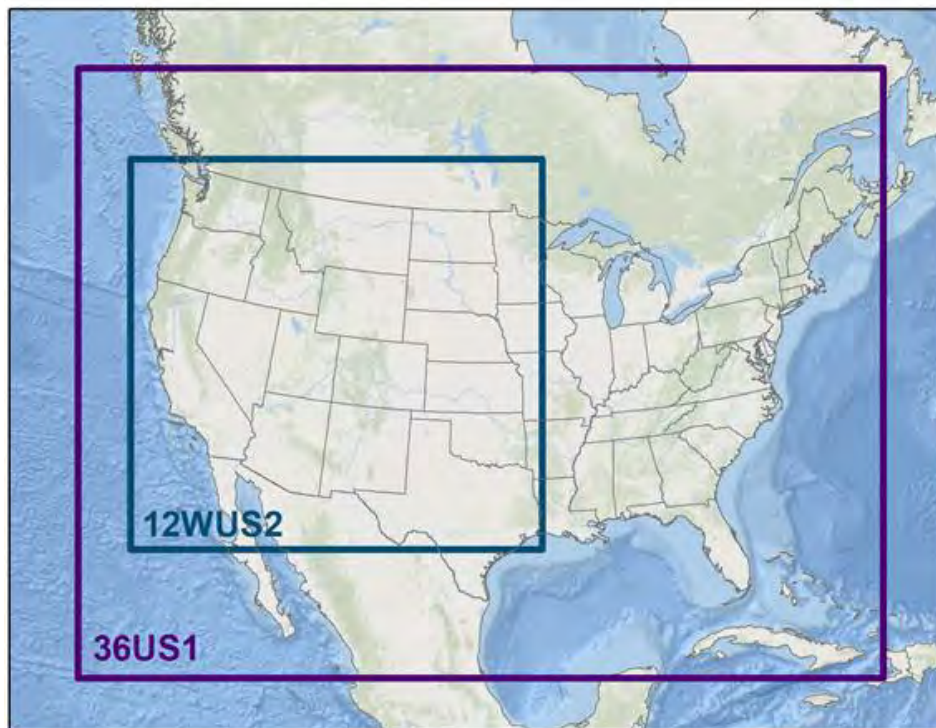

Table 2. Data sources for WRAP emissions sectors for the 12-km 12WUS2 and 36-km US domains for the 2014v2, Representative Baseline (RepBase2) and 2028 On the Books (2028OTBa2) scenarios.

4.0 Model Development:

The [WRAP-WAQs 2014 modeling platform](#) was developed and performed by Ramboll, Inc., under contract to WESTAR-WRAP. The 2014 modeling platform used the Weather Research and Forecasting (WRF) meteorological model, the Sparse Matrix Operator Kernel Emissions (SMOKE) model and the Comprehensive Air Quality Model with Extensions (CAMx) to project air quality for the 2014 base year. The Goddard Earth Observing System global chemical model (GEOS-Chem) provided global boundary conditions for the regional CAMx model for the 2014 base year. The CAMx 2014v2 final model configuration is defined in Table 1 of the WRAP-WAQs 2014 modeling platform webpage. CAMx version 7beta 6 was used for the 2014v2 model performance run, while CAMx version 7.0 was used for the subsequent model scenarios. **Figure 1** below illustrates the CAMx 36-km modeling domain covering the Continental United States and the 12-km modeling domain covering the western states.

Figure 1. 36-km continental U.S. (36US1) and 12-km western U.S. (12US2) modeling domains used in the [WRAP-WAQs 2014 modeling platform](#).

In addition to the 2014v2 model year, model runs were made using 2014 meteorology and with Representative Baseline (2014-2018, RepBase2), 2028 On the Books (2028OTBa2), 2028 Potential Additional Controls (2028PAC2), 2002 Hindcast, and Future Fire Sensitivities emission scenarios. Details are provided in model run specification sheets:

- [Representative Baseline \(RepBase2\) and 2028 On the Books \(2028OTBa2\) CAMx simulations](#)
- [Dynamic Evaluation – 2002 Simulations](#)
- [Future Fire Sensitivity Simulations](#)

5.0 WRAP-WAQS 2014v2 model performance

The [WRAP-WAQS 2014v2 modeling platform](#) webpage includes statistical model performance measures compared to EPA goals and criteria, spatial data plots and timeseries plots for the aerosol species listed below. For aerosol species concentrations, CAMx 2014v2 model outputs are compared to 2014 observations from the IMPROVE, [Chemical Speciation Network \(CSN\)](#) and Clean Air Status and Trends [\(CASTNET\) monitoring network](#).

- Ozone model performance is reported on the [Intermountain West Data Warehouse](#).

CAMx 2014v2 performance was evaluated using the [EPA Atmospheric Model Evaluation tool \(AMET\)](#) to compare model outputs to 2014 ambient air quality measurements (in $\mu\text{g}/\text{m}^3$) for:

- Particulate matter less than 2.5 micrometers (PM_{2.5})
- Nitrate (NO₃)
- Sulfate (SO₄)
- Organic mass from carbon (OMC)
- Elemental carbon (EC)
- Fine soil (Soil)
- Coarse mass (particulate matter between 2.5 and 10 micrometers).
- Seasalt: performance is tracked separately for Sodium and Chloride

For example, **Figures 2a to 2d** are spatial plots of the Normalized Mean bias statistic for the winter months January - March and Summer months July – September, for Nitrate and Sulfate, respectively. IMPROVE sites are illustrated as circles, CSN sites as triangles, and CASTNET sites as squares. In Winter, Nitrate is overpredicted in the Pacific Northwest and CA and underpredicted in the northern plains. Performance is generally mixed in the Rocky Mountains and Southwestern interior. In Summer, Nitrate is overpredicted in the Pacific Northwest and under predicted in CA. Sulfate is generally overpredicted in the Pacific Northwest in winter and underpredicted in the Southwest in summer.

Figure 2a. Normalized mean bias for 2014v2 modeled Nitrate compared to the IMPROVE, CSN, and CASTNET monitoring networks for Winter (Jan – Mar). ([2014v2 MPE summary](#))

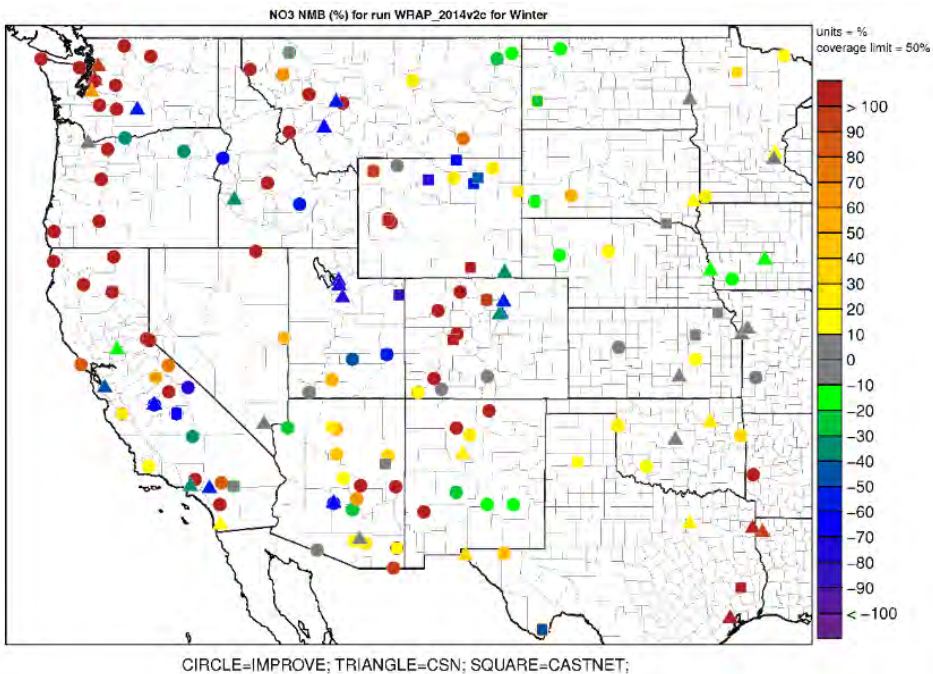

Figure 2b. Normalized mean bias for 2014v2 modeled Nitrate compared to the IMPROVE, CSN, and CASTNET monitoring networks for Summer (Jul – Sep). ([2014v2 MPE summary](#))

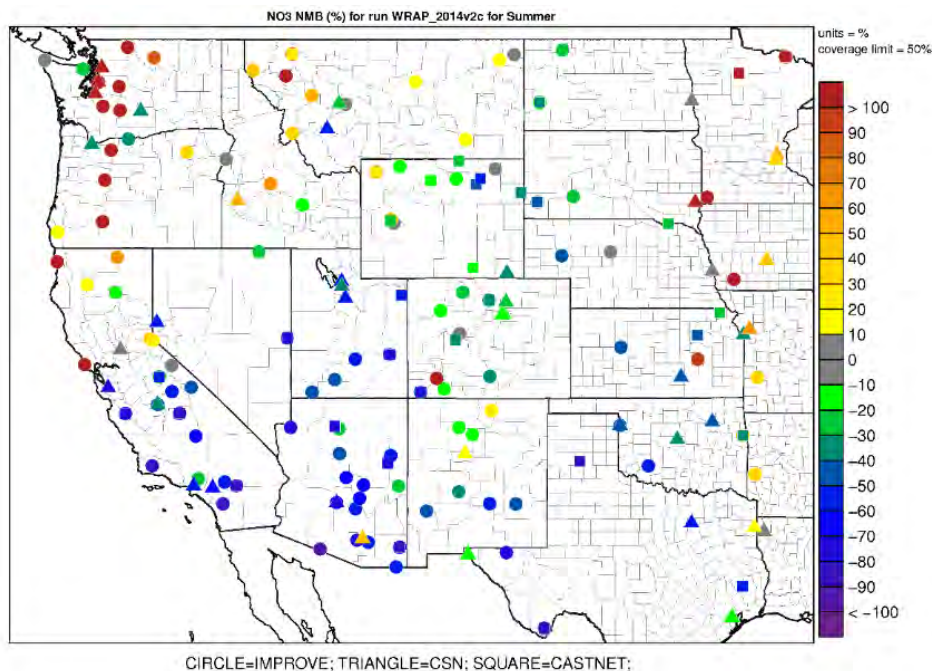

Figure 2c. Normalized mean bias for 2014v2 modeled Sulfate compared to the IMPROVE, CSN, and CASTNET monitoring networks for Winter (Jan – Mar). ([2014v2 MPE summary](#))

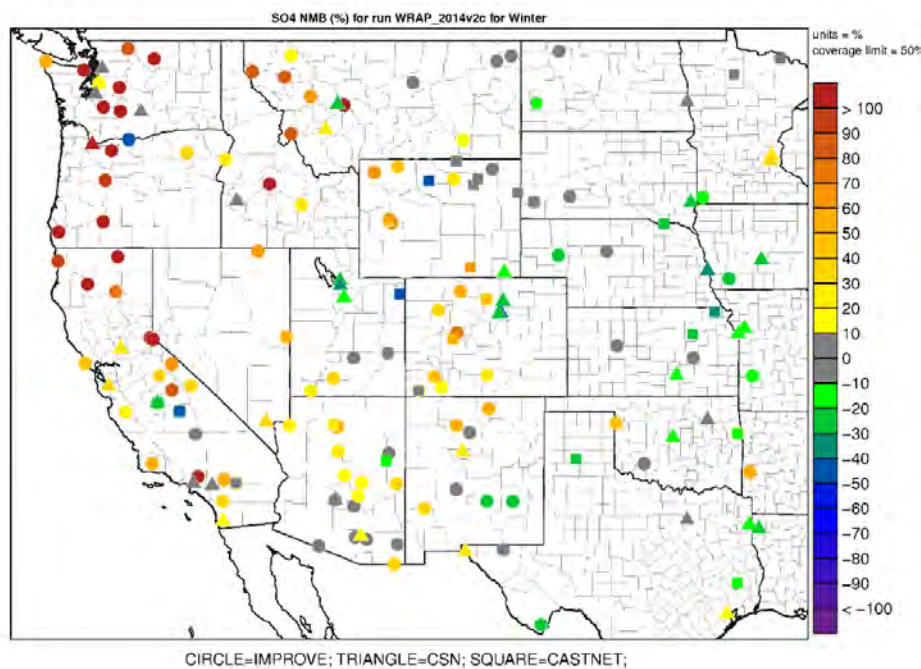

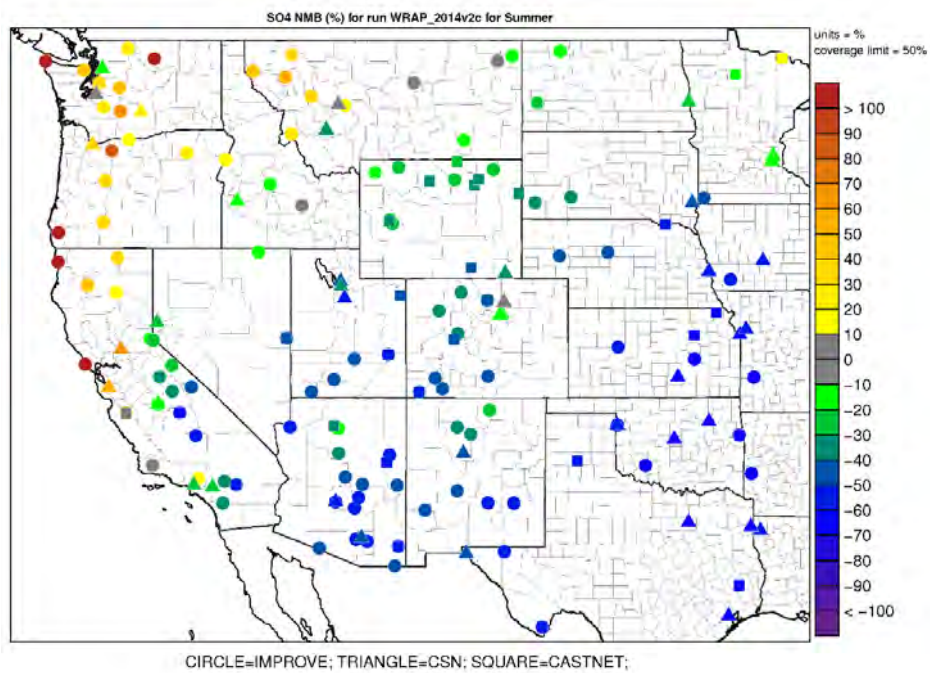

Figure 2d. Normalized mean bias for 2014v2 modeled Sulfate compared to the IMPROVE, CSN, and CASTNET monitoring networks for Summer (Jul – Sep). ([2014v2 MPE summary](#))

CAMx 12-km gridded annual anthropogenic nitrogen oxide and anthropogenic sulfur dioxide emissions (tons per year) for 2028OTBa emissions (from the WRAP 2028 [Weighted Emissions Potential](#) analyses) are mapped in **Figures 3a and 3b**.

Figure 3a. 2028 On the Books CAMx gridded 12-km annual anthropogenic nitrogen oxide emissions (tons per year) ([Weighted Emissions Potential](#))

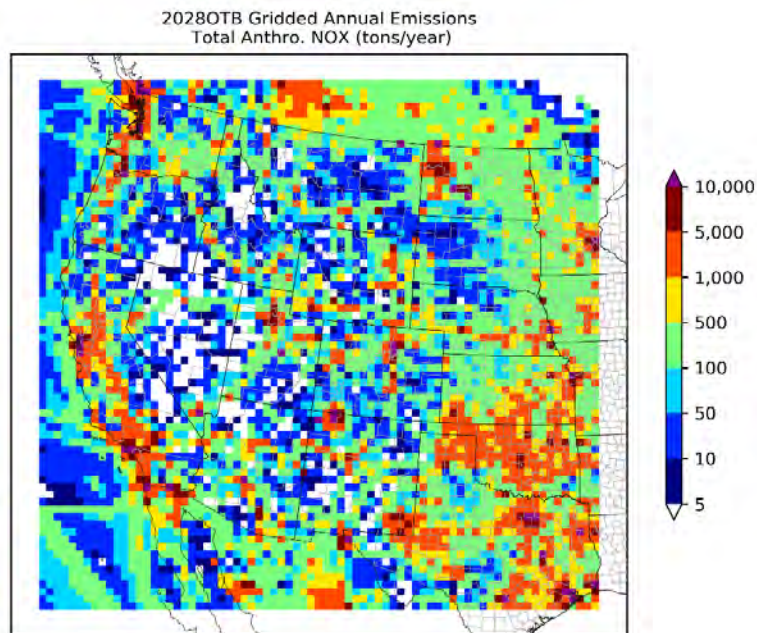

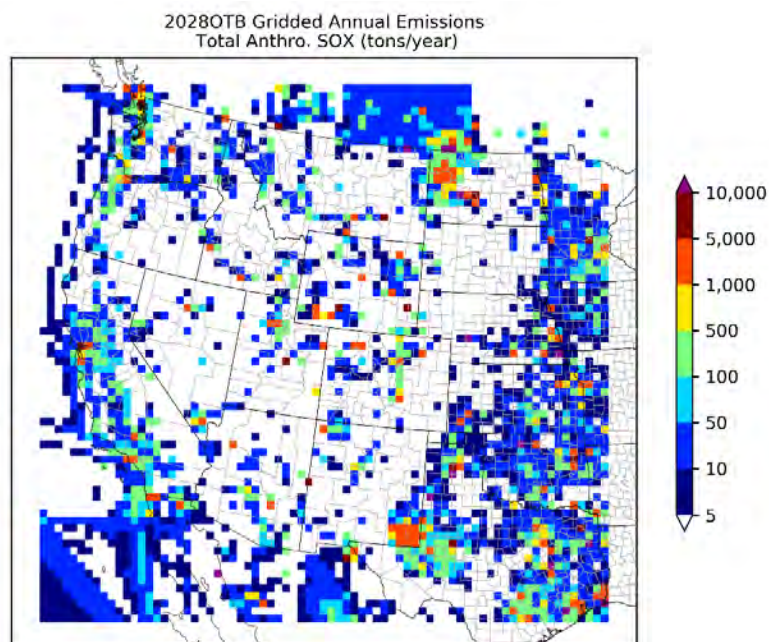

Figure 3b. 2028 On the Books CAMx gridded 12-km annual anthropogenic sulfur oxides emissions (tons per year) ([Weighted Emissions Potential](#))

6.0 Model Comparisons to Observations

Yellowstone National Park, in a fire-dominated ecosystem in the northern Rocky Mountains, and Mesa Verde National Park, in a drier southwestern ecosystem, are used as example Class I areas to interpret WESTAR-WRAP 2014v2 model performance, source contributions to haze, and projected visibility progress by 2028.

Comparisons of 2014 IMPROVE observations to the 2014v2, RepBase2, and 2028OTBa2 model scenarios are illustrated in **Figures 7a through 7d** ([TSS Modeling Express Chart #1](#)) for IMPROVE monitors in Yellowstone (YELL2) and Mesa Verde (MEVE1) National Parks, respectively. The charts display speciated aerosol light extinction for the averages of the most impaired days or clearest days. These are absolute model results; the model outputs are not adjusted to IMPROVE data. Comparison of 2014 IMPROVE observations to 2014v2 model results illustrates the accuracy of the model performance on the selected days. Comparison of the 2014v2, RepBase2, and 2028OTBa2 model scenario results demonstrates the aerosol responses to changes in emissions across these scenarios. Natural, fire, and international emissions are held constant at RepBase2 levels in 2028OTBa2, so the only differences between the two scenarios are due to changes in U.S. anthropogenic emissions.

Interpretation: Comparing 2014 IMPROVE observations to 2014v2 model results on most impaired days (**Figures 7a and 7b**) at both YELL2 and MEVE1, ammonium sulfate, elemental carbon, and coarse mass are under predicted, while ammonium nitrate and organic carbon are over predicted. At both YELL2 and MEVE1 organic carbon is slightly higher in RepBase2 than 2014v2; this reflects changes for wildfire emissions in the RepBase2 scenario. At both YELL2 and MEVE1 ammonium nitrate shows small reductions between the RepBase2 and 2028OTBa2 scenarios, all other aerosol species show little change.

On the clearest days at both YELL2 and MEVE1 (**Figure 7c and 7d**) all aerosol species are overestimated, likely because aerosol concentrations are very low and small differences in light extinction are reflected as large percentage differences.

TSS Modeling Express charts for the clearest days are formatted the same as for the most impaired days and will not be displayed in this document forward.

Figure 4a. Model Scenarios Compared to 2014 IMPROVE Observations for Aerosol Light Extinction (Mm^{-1}) on the most impaired days at the Yellowstone National Park (YELL2) IMPROVE monitor. [TSS Modeling Express Chart #1](#)

Figure 4b. Model Scenarios Compared to 2014 IMPROVE Observations for Aerosol Light Extinction (Mm^{-1}) on the most impaired days at the Mesa Verde National Park (MEVE1) IMPROVE monitor. [TSS Modeling Express Chart #1](#)

Figure 4c. Model Scenarios Compared to 2014 IMPROVE Observations for Aerosol Light Extinction (Mm^{-1}) on the clearest days at the Yellowstone National Park (YELL2) IMPROVE monitor. [TSS Modeling Express Chart #1](#)

Figure 4d. Model Scenarios Compared to 2014 IMPROVE Observations for Aerosol Light Extinction (Mm^{-1}) on the clearest days at the Mesa Verde National Park (MEVE1) IMPROVE monitor. [TSS Modeling Express Chart #1](#)

Figures 5a and 5b display [TSS Modeling Express Chart #2](#) for daily 2014 IMPROVE most impaired days at Yellowstone (YELL2) and Mesa Verde (MEVE1) National Parks, respectively, compared to the 2014v2, RepBase2, and 2028OTBa2 model scenarios.

Interpretation: Overall, comparing 2014 IMPROVE data to the 2014v2 modeled aerosol light extinction, CAMx showed credible skill for most impaired days at YELL2 and MEVE1. Maximum IMPROVE daily aerosol extinction on most impaired days is 24 Mm^{-1} at YELL2 and 20 Mm^{-1} at MEVE1. Daily ammonium nitrate (AmmNO_3) is well represented on most impaired days at these two sites. On a few most impaired days at both YELL2 and MEVE1, 2014v2 modeled ammonium sulfate (AmmSO_4) is more than 50% lower than IMPROVE observations. Under estimates of coarse mass are likely due to poor model skill in representing windblown dust. At both sites, organic carbon (OMC) is a large fraction of total aerosol extinction on several 2014 IMPROVE most impaired days. OMC is somewhat over predicted on several days. Differences in OMC on the most impaired days between the 2014v2 and RepBase2 scenarios are likely due to differences in wildfire activity assumptions for RepBase2 (covering the period the 2014 to 2018) compared to the single year 2014v2. Differences in total aerosol extinction between RepBase2 and 2028OTBa2 are small on all most impaired days, indicating little visibility progress.

Figure 5a. Model Scenarios Compared to 2014 IMPROVE Observations for Aerosol Light Extinction (Mm^{-1}) on most impaired days at the Yellowstone National Park (YELL1) IMPROVE monitor. [TSS Modeling Express Chart #2](#)

Figure 5b. Model Scenarios Compared to 2014 IMPROVE Observations for Aerosol Light Extinction (Mm^{-1}) on most impaired days at the Mesa Verde National Park (MEVE1) IMPROVE monitor. [TSS Modeling Express Chart #2](#)

7.0 2028 Visibility Projections

2028 visibility projections for the most impaired or clearest days are calculated following [EPA guidance](#) for ozone, PM_{2.5} and regional haze modeling (November 2018) using the EPA default projection method and using two WRAP alternative projection methods that are intended to reduce aerosol contributions from sources other than U.S. anthropogenic emissions on the most impaired days.

The EPA recommended projection procedures are used for all three WRAP projection methods (see [WRAP Procedures for Making Visibility Projections and Adjusting Glidepaths](#), March 2021 final draft.) [EPA's Software for the Model Attainment Test \(SMAT\)](#) was used to perform the projection calculations. CAMx model results are used in a relative sense, meaning that the aerosol concentrations are scaled to the IMPROVE monitoring data for the 2014-2018 period. The fractional differences between the 2028OTBa2 and the RepBase2 modeled aerosol concentrations are used to define scaling factors, also called relative response factors (RRFs), that are calculated for each aerosol species on each 2014 IMPROVE most impaired day (or clearest day) and then averaged for all most impaired days (or clearest days). These average relative response factors are multiplied by the daily aerosol concentration on each most impaired day or clearest day for the IMPROVE 2014-2018 5-year period to define daily projected aerosol concentrations, as indicated by the equations below.

$$\text{Relative Response Factor, } \text{RRF}_{\text{SO}_4} = \sum 2028\text{OTBa2}_{\text{SO}_4} / \sum \text{RepBase2}_{\text{SO}_4}$$

$$\text{Projected_SO4}_{2028\text{OTBa2}} = \text{IMPROVE_SO4}_{2014-2018} \times \text{RRF}_{\text{SO4}}$$

The daily projected 2028 aerosol concentrations for each of the 2014-2018 IMPROVE most impaired days (or clearest days) are converted to light extinction and then converted to deciview. The daily deciview values are averaged for each year and the annual averages are averaged for the 5-year period to define the 2028 visibility projections. The three WRAP projection methods:

- The **EPA default projection method** follows EPA guidance without deviation.
- The **EPA without fire projection method** uses the same 2014 IMPROVE most impaired days as the EPA default projection method. RepBase2 and 2028OTBa2 modeled [source apportionment](#) results are used to identify and remove modeled aerosol contributions from U.S. wildfire, U.S. wildland prescribed fire, and Non-U.S. (Canada and Mexico) fire on these days. After modeled fire contributions have been removed from the daily aerosol values, the EPA default projection procedures are used to calculate the relative response factors and 2028 visibility projections.
- The **Modeled MID projection method** selects the modeled RepBase2 days with the highest fraction of modeled U.S. anthropogenic contributions as the modeled most impaired days for both the RepBase2 and 2028OTBa2 scenarios. RepBase2 and 2028OTBa2 modeled [source apportionment](#) results are used to remove the fire contributions from the modeled most impaired days before calculating relative response factors and 2028 visibility projections.

In [TSS Modeling Express Chart #3](#) users can choose to illustrate, for one, two, or three projection methods, for either the most impaired days or clearest days, the visibility projections for 2028 On the Books (2028OTBa2) or 2028 Potential Additional Controls (2028PAC2) in aerosol light extinction. These aerosol contributions are the basis for the 2028 visibility projections in deciview that define the regional haze tracking metric and are displayed in [TSS Modeling Express Chart #4](#) (see Section 8.0). Changes in aerosol species extinction across the 2028 projection scenarios and methods illustrate which aerosol species are responsible for the projected changes in the regional haze visibility tracking metric in deciviews.

Figures 6a and 6b illustrate the IMPROVE 2014-2018 aerosol contributions and the 2028OTBa2 visibility projections in aerosol light extinction using the 3 WRAP projection methods for Yellowstone and Mesa Verde National Parks, respectively.

Interpretation: For YELL2, AmmNO₃, OMC, and EC are projected to decrease between the 2014-2018 IMPROVE observations and modeled 2028OTBa2 following the EPA default projection methods. The EPA without fire method has slight decreases in OMC and EC compared to the EPA default method, while the Modeled MID method, which selects different days as most impaired, has slight decreases in OMC, EC, and AmmSO₄ (0.3 Mm⁻¹). At MEVE1, AmmNO₃ and AmmSO₄ are reduced slightly between 2014-2018 IMPROVE observations and

2028OTBa2 projections using EPA default methods. The EPA without fire and Modeled MID methods display slight changes to OMC and EC compared to the EPA default method. As will be illustrated under Section 10.0 Regional Source Apportionment, biogenic and anthropogenic sources of carbon are significant and unchanged fractions of OMC and EC at these two sites. Thus, for these two sites, removing fire contributions from most impaired days only changes a fraction of the total carbon and the EPA without fire projection method has only small changes in the 2028 visibility projection.

Nonetheless, WRAP recommended that EPA without fire projection method be the default 2028 visibility projection displayed because this method removes the contributions of fire on the most impaired days and most closely focuses on anthropogenic contributions to haze.

Figure 6a. 2028 Visibility Projections on most impaired days in Aerosol Light Extinction (Mm^{-1}) compared to 2014-2018 IMPROVE observations for Yellowstone National Park (YELL2). [TSS Modeling Express Chart #3](#)

Figure 6b. 2028 Visibility Projections on most impaired days in Aerosol Light Extinction (Mm^{-1}) compared to 2014-2018 IMPROVE observations for Mesa Verde National Park (YELL2). [TSS Modeling Express Chart #3](#)

8.0 Visibility Projections compared to the Uniform Rate of Progress Glidepath

[TSS Modeling Express Chart #4](#) displays 2028 visibility projections in deciview compared IMPROVE measurements for the period 2000-2018 and to the Uniform Rate of Progress (URP) glidepath as defined by [EPA guidance](#) (Dec 2018). The 2028 visibility projections in deciview are calculated from aerosol concentrations and extinction as described in Section 7. Users can also select to display chart data by aerosol light extinction for individual species or Total Light Extinction.

The URP glidepath is constructed (in deciviews) for the 20% most impaired days (MID) or clearest days using observations from the IMPROVE monitoring site representing a Class I area. The URP glidepath starts with the IMPROVE most impaired days for the 2000-2004 5-year baseline and draws a straight line to estimated natural conditions displayed for the year 2064. For clearest days, the goal is no degradation of visibility from the 2000-2004 5-year baseline, therefore the glidepath for clearest days is a straight line from the 2000-2004 baseline to 2064. In the second regional haze planning period, 2064 natural visibility condition estimates use the 15-year average of natural conditions on IMPROVE most impaired days in each year 2000-2014. IMPROVE annual average values are presented in this chart as points. IMPROVE 5-year average values are presented as solid lines covering the periods 2000-2004 and 2014-2018.

The 2028OTBa2 and 2028PAC2 visibility projections were processed using [EPA's Software for the Model Attainment Test \(SMAT\)](#) for the three WRAP projection methods described in Section 7 (see also [WRAP Procedures for Making Visibility Projections and Adjusting Glidepaths](#), March 2021 final draft):

- EPA default projection method
- EPA without fire projection method
- Modeled MID projection method

2028 On the Books (2028OTBa2) and 2028 Potential Additional Controls (2028PAC2) visibility projections in deciview are illustrated as points that can be compared to the Uniform Rate of Progress glidepath. A state can select among the 2028 projection methods to define a 2028 Reasonable Progress Goal (RPG) for a Class I area for Regional Haze planning purposes.

The 2028 visibility projection is compared to the URP Glidepath at 2028 to determine whether visibility at the Class I areas is projected to be on, above, or below the URP Glidepath. Comparison of 2028 projections to the URP Glidepath defines how well the modeled trend in visibility tracks the straight-line uniform rate of progress to 2064. [EPA guidance](#) (August 2019) clarifies that the URP Glidepath is not a bright line test for reasonable visibility progress by 2028 and describes additional considerations for defining reasonable progress. Uncertainties in the glidepath assumptions are discussed in the [U.S. Anthropogenic Emissions Rate of Progress](#) (September 2021) document.

Figures 7a and 7b display [TSS Modeling Express Chart](#) #4 results for the 2028OTBa2 scenario for Yellowstone and Mesa Verde National Parks, respectively. Users could choose to also display results for the 2028PAC2 control scenario. Regional source apportionment data discussed in Section 10 will assist interpretation of 2028 visibility projections displayed in Chart #4.

Interpretation: For YELL2 (**Figure 7a**), the IMPROVE annual average deciview for the most impaired days varies widely between 2000 to 2018 and the 2000-2018 monitoring trend line (blue line) is above the URP Glidepath (red line). The IMPROVE 2014-2018 5-year average deciview for the most impaired days intersects the URP glidepath. The 2028OTBa2 visibility projections for all 3 WRAP methods are above the URP glidepath, although the EPA without fire and Modeled MID projection methods yield slightly lower 2028 projections than the EPA default projection. The IMPROVE annual average deciview for the clearest days show steady improvement between 2000 and 2018 and the 2028OTBa2 projection indicates further improvement on the clearest days.

At MEVE1 (**Figure 7b**) the IMPROVE annual average deciview for the most impaired days shows a consistent reduction between 2000 and 2018. The IMPROVE 2000-2018 monitoring trendline and the IMPROVE 2014-2018 5-year average deciview for the most impaired days are well below the URP glidepath. All 3 projection methods for 2028OTBa2 are also well below the URP

glidepath. The clearest days at MEVE1 also show continuous improvement and the 2028OTBa2 projections are below the 2014-2018 5-year average deciview.

Figure 7a. 2028 Visibility Projections for clearest days and most impaired days, compared to the Uniform Rate of Progress Glidepath at the Yellowstone National Park (YELL2) IMPROVE monitor. [TSS Modeling Express Chart #4](#)

Figure 7b. 2028 Visibility Projections for clearest days and most impaired days, compared to the Uniform Rate of Progress Glidepath at the Mesa Verde National Park (MEVE1) IMPROVE monitor. [TSS Modeling Express Chart #4](#)

In general, western Class I areas near urban areas or major point sources demonstrate visibility improvement in the IMPROVE monitoring data between 2000 to 2018 and the 2028 visibility projections are below the URP glidepath. Ammonium nitrate and ammonium sulfate are major contributors on most impaired days at many of these sites, including Mesa Verde NP (see **Figure 6b**). Class I areas near oil and gas development do not display as much visibility improvement by 2028OTBa2 as more remote sites. Class I areas where carbon is a significant fraction of aerosol contributions on most impaired days, including Yellowstone NP (see **Figure 6a**) show more variable visibility progress in the IMPROVE monitoring data 2000-2018 and in the 2028 visibility projections.

Clearest days at all western Class I areas have improved between 2000 and 2018 and are projected to continue to improve by 2028 at almost all western Class I areas.

[EPA Volcanic adjustment](#) (August 2021) for IMPROVE monitors at Hawai'i Volcano (HAVO1) and Haleakalā (HALE1) National Parks:

EPA defined an adjustment to ammonium sulfate to account for episodic volcanic events at Hawai'i Volcano (HAVO1) and Haleakalā (HALE1) National Parks. EPA's adjustment follows the same methodology as defined in December 2018 guidance to account for episodic extreme fire or dust events using IMPROVE measurements of carbon or crustal materials. EPA's adjustment for volcanic contributions uses IMPROVE daily ammonium sulfate measurements for the years 2000-2014, defines the average 95th percentile value for each year, and selects the lowest annual value as the threshold to assign ammonium sulfate daily measurements above that threshold as episodic volcanic (natural) contributions. After accounting for episodic volcanic contributions to ammonium sulfate, impairment is calculated following EPA guidance. By assigning maximum ammonium sulfate values as natural rather than anthropogenic, the days that are defined as most impaired by anthropogenic contributions shift. Ammonium sulfate still dominates the most impaired days, suggesting that not all volcanic contributions are accounted for using a 95th percentile threshold.

In addition to the volcanic adjustment, to assure a complete IMPROVE data set for Haleakalā National Park, EPA also applied data substitution methods to merge data from two separate IMPROVE monitor locations that have represented the Haleakalā NP Class I area over the 2000-2018 period (HALE1 and Haleakala Crater, HACR1). The combined data set is referred to as HALE_RHTS.

EPA also provided 2028 visibility projections for the volcano adjusted data sets, HAVO1_VADJ and HALE_RHTS_VADJ, as described in EPA's [Technical Support Document for Updated 2028 Regional Haze Modeling for Hawaii, Virgin Islands, and Alaska](#) (August 2021). EPA 2028 visibility projections for HAVO1_VADJ and HALE_RHTS_VADJ are displayed in aerosol extinction in [TSS Modeling Express Chart #20](#) (equivalent to TSS Modeling Chart #3). [TSS Modeling Express Chart #21](#) (equivalent to TSS Modeling Chart #3) displays 2028 visibility projections in deciview

for HAVO1_VADJ and HALE_RHTS_VADJ, the 2000-2018 volcano-adjusted monitoring data, estimated natural conditions in 2064, and the Uniform Rate of Progress for the volcano adjusted data for the most impaired days or clearest days at these two Class I areas.

[TSS Modeling Express Tool](#) #8 displays a table for each state listing all federal Class I areas in that state comparing the 2014-2018 5-year average IMPROVE observations to the 2028OTBa2 and 2028PAC2 visibility projections in deciview, calculated using the 3 WRAP projection methods. **Table 11** illustrates the 2028 visibility projection results for the state of Colorado. Note that Colorado did not define Potential Additional Controls for sources in Colorado for 2028PAC2, nonetheless, small changes in visibility were projected for 2028PAC2 due to PAC2 control assumptions in other WRAP states.

Table 11. 2028 Visibility Projections for the most impaired days at Class I areas in Colorado for the 2028 On the Books (2028OTBa2) and 2028 Potential Additional Controls (2028PAC2) model scenarios and 3 WRPA projection methods. [TSS Modeling Express Tool](#) #8

1) U.S. EPA. December 2018. Technical Guidance on Tracking Visibility Progress for the Second Implementation Period of the Regional Haze Program. EPA-454/R-18-010

9.0 Adjustments to the Uniform Rate of Progress Glidepath

[EPA guidance](#) (December 2018) allows a State to propose an adjustment to the URP glidepath to account for visibility contributions from anthropogenic emissions outside the U.S. or from emissions from wildland prescribed fires that meet specific land management objectives and apply basic smoke management practices. The EPA Administrator may approve proposed

adjustments to the URP glidepath that follow “scientifically valid data and methods.” EPA’s regional haze modeling [Technical Support Document](#) (September 2019) demonstrates adjustments to the 2064 endpoint of the URP glidepath using source apportionment results for international anthropogenic or wildland prescribed fire emissions from the EPA 2028 model scenario.

WRAP methods to adjust the 2064 endpoints for the URP glidepath to account for international emissions or wildland prescribed fire emissions are described in detail in [WRAP Procedures for Making Visibility Projections and Adjusting Glidepaths](#) (March 2021). The WRAP adjustments to the URP glidepath are based on 2028OTBa2 source apportionment results for international anthropogenic and wildland prescribed fire. Consistent with the methods evaluated in the EPA Technical Support Document, WRAP evaluated five approaches using 2028OTBa2 source apportionment results to adjust the 2064 endpoints. 2028 source apportionment results were applied in a relative sense (model results normalized to 2028 visibility projections) or an absolute sense (unadjusted absolute model results). 2064 endpoints were defined using IMPROVE natural conditions estimated for 2000-2014 or using 2028 source apportionment results for natural source contributions.

After review of the initial glidepath adjustment results, WRAP recommended that adjustment of the URP glidepath for Class I areas in western states use 2028 source apportionment results in a relative sense and use EPA estimated natural conditions for the 2064 endpoint for one of two options:

- International anthropogenic contribution normalized to IMPROVE monitoring data and added to EPA estimated natural conditions (International).
- International anthropogenic plus Wildland Prescribed fire combined contributions normalized to IMPROVE monitoring data and added to EPA estimated natural conditions (International + wildland Rx fire)

Note that wildland prescribed fire events in the 2028 OTBa2 model scenario reflect the same events as modeled for 2014v2. Wildland prescribed fire events may not occur on most impaired days in 2014v2. Location, timing, frequency, magnitude, and duration of wildland prescribed fire events vary geographically, seasonally, and year to year. Therefore, interpretation of wildland prescribed fire contributions on most impaired days for the 2028OTBa2 source apportionment results and for the 2064 adjustment to the URP glidepath is uncertain.

[TSS Modeling Express Chart](#) #5 illustrates the Regional Haze Uniform Rate of Progress (URP) Glidepath as defined by EPA guidance and the two WRAP alternative glidepath end point adjustments for 2064 (International, International + Wildland Prescribed Fire.)

The URP glidepath (in deciviews) for most impaired days and the optional glidepath adjustments all start from the 2000-2004 5-year baseline for most impaired days and draw a straight line to estimated natural conditions in 2064. All 2064 endpoints use EPA estimates of natural conditions based on 2000-2014 IMPROVE data. Annual average deciview for 2000 to

2018 most impaired days are illustrated as points. IMPROVE 2000-2004 and 2014-2018 5-year average deciview values are illustrated as solid lines. Users can choose to display 2028OTBa2 and/or 2028PAC2 visibility projections for 1-3 projection methods and to display 2064 endpoint without adjustment or adjustment for either international anthropogenic emissions or international anthropogenic plus wildland prescribed fire emissions. The 2028OTBa2 EPA without fire projection method is the default setting for purposes of comparing 2028 visibility projections to the adjustment glidepath.

Figures 8a and 8b illustrate examples of [TSS Modeling Express Chart](#) #5 for Yellowstone (YELL2) and Mesa Verde (MEVE1) National Parks.

Interpretation: At YELL2, the 2028OTBa2 EPA without fire projection is above the URP glidepath. Adding International anthropogenic contributions to the 2064 endpoint raises the adjusted glidepath in 2028 to be above the 2028OTBa2 EPA without fire projection value. The second adjustment to the 2064 endpoint (adding wildland prescribed fire contribution to the international anthropogenic contribution) slightly raises the slope of the glidepath compared to international emissions alone.

At MEVE1, the 2028 visibility projection is below the URP glidepath. Adjustment of the 2064 endpoint for the international anthropogenic contribution raises the slope of the glidepath; adjustment for wildland prescribed fire has a negligible change to the adjusted glidepath.

At most Class I areas in the western U.S., application of the recommended methods to adjust the 2064 endpoint raises the slope of the URP glidepath. Western states will independently determine whether or not to use the URP glidepath adjustments in their regional haze planning.

Figure 8a. 2028 Visibility Projections compared to adjustments to the Uniform Rate of Progress Glidepath for most impaired days at the Yellowstone National Park (YELL2) IMPROVE monitor. [TSS Modeling Express Chart](#) #5.

Figure 8b. 2028 Visibility Projections compared to adjustments to the Uniform Rate of Progress Glidepath for most impaired days at the Mesa Verde National Park (MEVE1) IMPROVE monitor.
[TSS Modeling Express Chart #5](#)

10.0 Regional (High-level) Source Apportionment

WRAP Source Apportionment methods are described in the run specification sheet for [High-Level and Low-Level Source Apportionment Modeling](#) using the RepBase2 and 2028OTBa2 model scenarios (September 2020).

Purpose: Regional source apportionment results for U.S. anthropogenic, international anthropogenic, fire, and natural source contributions at each IMPROVE site representing western Class I areas were used as follows:

- Modeled most impaired days (ModMID) were defined based on RepBase2 source apportionment results. ModMID days were ranked by modeled U.S. anthropogenic contributions as a fraction of total aerosol light extinction. ModMID days are used as one of the WRAP alternative 2028 projection methods (see Section 7).
- 2028OTBa2 modeled international and U.S. wildland prescribed fire contributions were used as an option to adjust the 2064 endpoint of the URP glidepath for the most impaired days (see Section 9).
- Along with 2002 Hindcast scenario, RepBase2 and 2028OTBa2 regional source apportionment results for total aerosol light extinction were used to define a U.S. Anthropogenic Emissions Rate of Progress (see Section 12).

The CAMx photochemical model version 7.0 with the Particle Source Apportionment tool (PSAT) was applied at a regional level to separate U.S. anthropogenic contributions from those of fire, natural, and international anthropogenic contributions for the representative baseline period (2014-2018, RepBase2) and a future year, 2028OTBa2. CAMx with PSAT tracked gaseous and particle air emissions from sources through atmospheric dispersion, photochemical reactions, and transport to receptors (the 12-km modeling grid cell where the IMPROVE monitor is located), as defined in **Table 12**. Aerosol concentrations at the receptor include the direct products of primary gaseous and particle emissions and secondary aerosol formation.

Source contributions were defined for the following aerosols:

- Ammonium nitrate (AmmNO₃)
- Ammonium sulfate (AmmSO₄)
- Organic mass from carbon (OMC)
 - Primary Organic Aerosol (POA)
 - Secondary Organic Aerosols
 - Anthropogenic (SOAA)
 - Biogenic (SOAB)
- Primary Elemental Carbon (EC)
- Primary Fine Soil
- Primary Coarse Mass
- Seasalt

Table 12. PSAT emissions tracers mapped to IMPROVE aerosol species at the model receptor

PSAT Tracer Description	IMPROVE Species Name (TSS label)	Mapping between IMPROVE and PSAT species (concentration in $\mu\text{g}/\text{m}^3$)	Notes
Particulate Sulfate (PS4)	Ammonium Sulfate (AmmSO4)	$\text{AmmSO}_4 = 1.375 * \text{PS}_4$	Factor 1.375 converts sulfate ion to fully neutralized ammonium sulfate
Particulate Nitrate (PN3)	Ammonium Nitrate (AmmNO3)	$\text{AmmNO}_3 = 1.29 * \text{PN}_3$	Factor 1.29 converts nitrate ion to fully neutralized ammonium nitrate
Primary Elemental Carbon (PEC)	Elemental Carbon (EC)	$\text{EC} = \text{PEC}$	
Primary Organic Aerosol (POA)	Organic Mass from Carbon (OMC)	$\text{OMC} = \text{POA} + \text{SOAA} + \text{SOAB}$	Secondary Organic Aerosols (SOA) are not explicitly tracked by source group. SOA are derived from AVRG concentration files and are operationally assigned to anthropogenic (SOAA) or biogenic (SOAB) source groups. All SOAA is assigned to U.S. anthropogenic source category and all SOAB is assigned to Natural source category.
Aluminum (PAL)	Fine Soil (Soil)	$\text{Soil} = 2.2 * \text{PAL} + 2.49 * \text{PSI} + 1.63 * \text{PCA} + 2.42 * \text{PFE} + 1.94 * \text{PTI}$	Soil mapping is consistent with IMPROVE definition
Silicon (PSI)			
Calcium (PCA)			
Iron (PFE)			
Titanium (PTI)			
Coarse Crustal PM (PCC)	Coarse Mass (CM)	$\text{CM} = \text{PCC} + \text{PCS}$	
Other Coarse Particulate (PCS)			
Chloride (PCL)	Sea Salt	$\text{Sea Salt} = 1.8 * \text{PCL}$	Chloride is not tracked by Source Apportionment. It is obtained from the AVRG concentration files. All Chloride is assigned to sea salt. All sea salt is assigned to the "natural" source group. All other source group contributions to sea salt are 0.

Due to computational constraints, the secondary organic aerosols (SOA) family of reactive tracers were not used to track SOA at the receptor; rather SOA were operationally assigned to anthropogenic (SOAA) or biogenic (SOAB) contributions based on the chemical signatures (e.g., isoprene was assigned as biogenic in origin; benzene was assigned as anthropogenic in origin.) For purposes of compositing regional source categories, all SOAA were assigned to the U.S. anthropogenic source category and all SOAB were assigned to the Natural source category.

Regional source apportionment results for RepBase2 and 2028OTBa2 aerosol light extinction are displayed in [TSS Modeling Express Tools](#) # 10-16 for 15 source groups that are composited into 6 source categories as listed below. Abbreviations correspond to the source labels used in TSS Modeling Express Tools #10-16.

- U.S. Anthropogenic (USAnthro)
 - U.S. anthropogenic (AntUS)
 - U.S. agricultural fire (AgfireUS)
 - Secondary Organic Aerosol-Anthropogenic (SOAA)
 - Commercial Marine Vessels (CMVUS)
 - U.S. anthropogenic contributions from outside the CAMx 36-km domain boundary as defined by the GEOS-Chem global model. (BC-US)
- U.S. Wildfire (WFUS)
- U.S. Wildland Prescribed fire (RxUS)
- Canadian and Mexican fires (OthFr)
- Natural
 - Natural (Nat)
 - Secondary Organic Aerosol -Biogenic (SOAB)
 - Natural contributions from outside the CAMx 36-km domain boundary as defined by the GEOS-Chem global model. (BC-Nat)
- International Anthropogenic (IntlAnthro)
 - International Anthropogenic contributions from outside the CAMx 36-km domain boundary as defined by the GEOS-Chem global model. (BC-Int)
 - Canadian Anthropogenic (AntCAN)
 - Mexican Anthropogenic (AntMEX)
 - Commercial Marine vessels – International (beyond 200km from U.S. coast) (CMV_nonUS)

Users can choose to display source apportionment results in [TSS Modeling Express Tools](#) # 10-16 for most impaired days (EPA default 2014 IMPROVE days), modeled most impaired days, or clearest days. Charts in this document provide examples for 2014 IMPROVE most impaired days only.

Users can choose to display source apportionment results for total aerosol extinction or for individual aerosols species extinction.

Modeled source contributions to light extinction in [TSS Modeling Express Tools](#) # 10-16 are not normalized to IMPROVE monitoring data. Model performance should be considered when interpreting source apportionment results. Average and daily model performance for most impaired days as displayed in [TSS Modeling Express Tool](#) # 1 and 2 provide insight to confidence to place in source apportionment results for individual aerosol species.

[TSS Modeling Express Tool](#) # 10 defines in a single stacked barchart the light extinction contributions from 15 source groups for the RepBase2 or 2028OTBa2 model scenarios. **Figures 9a and 9b** illustrate regional source apportionment for 2028OTBa2 for Yellowstone NP (YELL2) and Mesa Verde NP (MEVE1), respectively.

Interpretation: At YELL2, U.S. anthropogenic emissions in 2028OTBa2 are projected to contribute less than 20% of total aerosol light extinction (left chart) and less than 30% of extinction due to AmmNO₃ extinction (right chart). At MEVE1, U.S. anthropogenic emissions in 2028OTBa2 are projected to contribute less than 30% of total extinction (left) and 54% of AmmNO₃ extinction (right).

Figure 9a. 2028OTBa2 Regional Source Apportionment for most impaired days at the Yellowstone National Park (YELL2) IMPROVE monitor for 15 source group contributions to total aerosol light extinction (Mm^{-1}) (left) or to Ammonium nitrate light extinction (right). [TSS Modeling Express Tool](#) # 10.

Figure 9b. 2028OTBa2 Regional Source Apportionment for most impaired days at the Mesa Verde National Park (MEVE1) IMPROVE monitor for 15 source group contributions to total aerosol light extinction (Mm^{-1}) (left) or to Ammonium nitrate light extinction (right). [TSS Modeling Express Tool](#) # 10.

[TSS Modeling Express Tool](#) # 11, illustrated in **Figure 10a** for YELL2 and **Figure 10b** for MEVE1, displays speciated aerosol light extinction on most impaired days for RepBase2 or 2028OTBa2, by pollutant, for each of 6 source categories.

Interpretation: For YELL2, in 2028OTBa2, the natural source category is the largest source contribution, even on the most impaired days. Organic carbon dominates the natural and fire categories. International anthropogenic source contributions are equal to U.S. anthropogenic contributions and smaller than natural plus fire contributions. Ammonium sulfate and ammonium nitrate dominate the international anthropogenic category. For U.S. anthropogenic contributions, ammonium nitrate, ammonium sulfate, organic carbon, and coarse mass are projected to have similar contributions. U.S. wildland prescribed fire has very small contributions at YELL2.

The 2028OTBa2 visibility projections for YELL2 are projected to be above the URP glidepath (see **Figure 7a**, [TSS Modeling Express Tool](#) # 4) because U.S. anthropogenic sources are a smaller fraction of total aerosol extinction compared to natural, international, and fire contributions. Adding the 2028OTBa2 international contribution to the 2064 endpoint raises the URP glidepath above the 2028OTBa2 visibility projection for YELL2 (see **Figure 8a**, [TSS Modeling Express Tool](#) # 5). Adding 2028OTBa2 wildland prescribed fire to the 2064 endpoint has a very small impact on the slope of the URP glidepath because U.S. wildland prescribed fire has a small contribution to total aerosol extinction.

Figure 10a. 2028OTBa2 Regional Source Apportionment of Speciated Aerosol Light Extinction (Mm^{-1}) for most impaired days at the Yellowstone National Park (YELL2) IMPROVE monitor for U.S. Anthropogenic, International anthropogenic, Natural, and Fire source categories, with component species contributions. [TSS Modeling Express Tool](#) # 11.

Interpretation: For MEVE1, in 2028OTBa2, U.S. anthropogenic emissions have the largest contributions to total aerosol extinction, divided between ammonium sulfate, ammonium nitrate, organic carbon, and coarse mass (**Figure 10b**). International anthropogenic and natural sources have equivalent, somewhat smaller contributions than U.S. anthropogenic sources. International anthropogenic contributions are dominated by ammonium sulfate, while natural sources and fires are dominated by organic carbon. U.S. wildland prescribed fire has very small contributions at MEVE1.

The 2028OTBa2 visibility projections for MEVE1 are projected to be below the URP glidepath (see **Figure 10a**, [TSS Modeling Express Tool](#) # 4) because U.S. anthropogenic sources are a larger fraction of total aerosol extinction compared to natural, international, and fire contributions and changes in the U.S. anthropogenic emissions between RepBase2 and 2028OTBa2 are reflected in changes to 2028OTBa2 visibility projections. Adding the 2028OTBa2 international contribution to the 2064 endpoint raises the URP glidepath for MEVE1 (see **Figure 11a**, [TSS Modeling Express Tool](#) # 5). Adding 2028OTBa2 wildland prescribed fire to the 2064 endpoint has a very small impact on the slope of the URP glidepath because U.S. wildland prescribed fire has a small contribution to total aerosol extinction.

Figure 10b. 2028OTBa2 Regional Source Apportionment of Speciated Aerosol Light Extinction (Mm^{-1}) for most impaired days at the Mesa Verde National Park (MEVE1) IMPROVE monitor for U.S. Anthropogenic, International anthropogenic, Natural, and Fire source categories, with component species contributions. [TSS Modeling Express Tool](#) # 11.

[TSS Modeling Express Tool](#) # 12 illustrated in **Figure 11a** for Yellowstone NP, YELL2, and **Figure 11b** for Mesa Verde NP, MEVE1, displays speciated aerosol light extinction on most impaired days for RepBase2 or 2028OTBa2, by source category, for each of 7 pollutants.

Interpretation: At YELL2, in 2028OTBa2, on the most impaired days, organic carbon is the largest contributor to total aerosol extinction and natural and fire sources are the largest contributors to organic carbon. International anthropogenic emissions are the largest contributor to AmmSO₄. Natural, international anthropogenic, and U.S. anthropogenic emissions have comparable contributions to AmmNO₃.

At MEVE1, in 2028OTBa2, on most impaired days, AmmSO₄ and organic carbon are the largest contributors to total aerosol extinction. International emissions are the largest contributor to AmmSO₄ and natural emissions are the largest contributor to organic carbon. U.S. anthropogenic emissions are the second largest contributors to AmmSO₄ and organic carbon.

Figure 11a. 2028OTBa2 Regional Source Apportionment of Speciated Aerosol Light Extinction (Mm^{-1}) for most impaired days at the Yellowstone National Park (YELL2) IMPROVE monitor for 7 pollutants, with component U.S. Anthropogenic, International anthropogenic, Natural, and Fire contributions to each pollutant. [TSS Modeling Express Tool](#) # 12.

Figure 11b. 2028OTBa2 Regional Source Apportionment of Speciated Aerosol Light Extinction (Mm^{-1}) for most impaired days at the Mesa Verde National Park (MEVE1) IMPROVE monitor for 7 pollutants, with component U.S. Anthropogenic, International anthropogenic, Natural, and Fire contributions to each pollutant. [TSS Modeling Express Tool](#) # 12.

[TSS Modeling Express Tool](#) # 13 illustrated in **Figure 12a** for Yellowstone NP (YELL2) and **Figure 12b** for Mesa Verde NP (MEVE1), displays aerosol light extinction on individual 2014 IMPROVE most impaired days for RepBase2 or 2028OTBa2 source apportionment, by source category.

Interpretation: Comparing Figures 15a and 15b, U.S. anthropogenic contributions in 2028OTBa2 are a larger fraction of daily aerosol light extinction at Mesa Verde NP than at Yellowstone NP. U.S. anthropogenic contributions dominate on the two most impaired days with the highest total aerosol extinction at MEVE1. At YELL2, international anthropogenic and natural sources are equal or greater contributors to daily aerosol light extinction than U.S. anthropogenic sources. These source apportionment results are consistent with the 2028OTBa2 visibility projections for these two sites (see **Figure 7a**, [TSS Modeling Express Tool](#) # 4).

Figure 12a. 2028OTBa2 Regional Source Apportionment of Aerosol Light Extinction (Mm^{-1}) for 2014 IMPROVE daily most impaired days at the Yellowstone National Park (YELL2) IMPROVE monitor for U.S. Anthropogenic, International anthropogenic, Natural, and Fire emissions. [TSS Modeling Express Tool](#) # 13.

Figure 12b. 2028OTBa2 Regional Source Apportionment of Aerosol Light Extinction (Mm^{-1}) for daily 2014 IMPROVE most impaired days at the Mesa Verde National Park (MEVE1) IMPROVE monitor for U.S. Anthropogenic, International anthropogenic, Natural, and Fire emissions. [TSS Modeling Express Tool](#) # 13.

[TSS Modeling Express Tool](#) # 14 illustrated in **Figures 13a and 13b** for Yellowstone NP (YELL2) and **Figures 13c and 13d** for Mesa Verde NP (MEVE1) displays RepBase2 or 2028OTBa2 source apportionment results as a treemap (used to display hierarchal data.) Source categories are displayed in block colors with component source groups outlined within each source category total. Users can choose to display source apportionment results for total aerosol light extinction or single aerosol species extinction. Results in Figures 13a and 13c display total aerosol light extinction for 2028OTBa2; results in Figures 13b and 13d display light extinction due to AmNO_3 for 2028OTBa2.

Interpretation: at YELL2, for total aerosol extinction, natural sources are the largest contributors. International anthropogenic and U.S. anthropogenic have similar contributions, and wildfire is also an important source contribution. For AmNO_3 , Natural, International anthropogenic and U.S. anthropogenic sources have very similar contributions. As shown in Figure 9a, at YELL2, U.S. anthropogenic emissions in 2028OTBa2 are projected to contribute less than 20% of total aerosol light extinction and less than 30% of extinction due to AmNO_3 . These low fractions mean that it is more difficult to demonstrate changes visibility in response to changes in U.S. anthropogenic emissions.

At MEVE1, U.S. anthropogenic emissions are the largest source category for total aerosol extinction and for extinction due to AmNO_3 (Figures 13c, 13d). Visibility is more likely to respond to changes in U.S. anthropogenic emissions at MEVE1 than at YELL2.

Figure 13a. 2028OTBa2 Regional Source Apportionment of Total Aerosol Light Extinction (Mm^{-1}) for most impaired days at the Yellowstone National Park (YELL2) for source groups contributing to U.S. Anthropogenic, International anthropogenic, Natural, and Fire source categories. [TSS Modeling Express Tool](#) # 14.

Figure 13b. 2028OTBa2 Regional Source Apportionment of Aerosol Light Extinction (Mm^{-1}) due to Ammonium nitrate for most impaired days at the Yellowstone National Park (YELL2) for source groups contributing to U.S. Anthropogenic, International anthropogenic, Natural, and Fire source categories. [TSS Modeling Express Tool](#) # 14.

Figure 13c. 2028OTBa2 Regional Source Apportionment of Total Aerosol Light Extinction (Mm^{-1}) for most impaired days at the Mesa Verde National Park (MEVE1) for source groups contributing to U.S. Anthropogenic, International anthropogenic, Natural, and Fire source categories. [TSS Modeling Express Tool](#) # 14.

Figure 13d. 2028OTBa2 Regional Source Apportionment of Aerosol Light Extinction (Mm^{-1}) due to Ammonium Nitrate for most impaired days at the Mesa Verde National Park (MEVE1) for source groups contributing to U.S. Anthropogenic, International anthropogenic, Natural, and Fire source categories. [TSS Modeling Express Tool](#) # 14.

[TSS Modeling Express Tool](#) # 15 illustrated in **Figure 14a** for Yellowstone NP (YELL2) and **Figure 14b** for Mesa Verde NP (MEVE1), displays RepBase2 or 2028OTBa2 source apportionment results as a treemap (used to display hierarchical data.) Source categories are displayed in block colors with component aerosol species contributions outlined within each source category total. Users can choose to display source apportionment results for total aerosol light extinction or single aerosol species extinction. Results in Figures 14a and 14b display total aerosol light extinction for 2028OTBa2.

The same data are presented in TSS Modeling Express Tool #11 (Figures 10a and 10b.)

Interpretation: the tree map shows the aerosol species contributions to each source category. At both YELL2 and MEVE1, OMC is a large fraction of U.S. anthropogenic contributions, in addition to AmmNO3 and AmmSO4. OMC is also a large fraction of natural and fire contributions.

Figure 14a. 2028OTBa2 Regional Source Apportionment of Total Aerosol Light Extinction (Mm^{-1}) for most impaired days at the Yellowstone National Park (YELL2) for aerosol species contributions to U.S. Anthropogenic, International anthropogenic, Natural, and Fire source categories. [TSS Modeling Express Tool](#) # 15.

Figure 14b. 2028OTBa2 Regional Source Apportionment of Total Aerosol Light Extinction (Mm^{-1}) for most impaired days at the Mesa Verde National Park (MEVE1) for aerosol species contributions to U.S. Anthropogenic, International anthropogenic, Natural, and Fire source categories. [TSS Modeling Express Tool](#) # 15.

[TSS Modeling Express Tool](#) # 16 illustrated in **Figure 15a** for Yellowstone NP (YELL2) and **Figure 15b** for Mesa Verde NP (MEVE1), displays RepBase2 or 2028OTBa2 source apportionment results as a treemap (used to display hierarchical data.) Aerosol species contributions are displayed in block colors with component source groups outlined within each aerosol species total. Users can choose to display source apportionment results for total aerosol light extinction or single aerosol species extinction. Results in Figures 15a and 15b display total aerosol light extinction for 2028OTBa2.

The same data are presented in TSS Modeling Express Tool #12 (Figures 11a and 11b.)

Interpretation: at YELL2, U.S. anthropogenic contributions are the third most important for OMC, AmmSO4, and AmmNO3. At MEVE1 U.S. anthropogenic contributions are the largest factor for AmmNO3 and the second largest for AmmSO4 and OMC.

Figure 15a. 2028OTBa2 Regional Source Apportionment of Total Aerosol Light Extinction (Mm^{-1}) for most impaired days at Yellowstone National Park (YELL2) for source category contributions to individual aerosol species. [TSS Modeling Express Tool](#) # 16.

Figure 15b. 2028OTBa2 Regional Source Apportionment of Total Aerosol Light Extinction (Mm^{-1}) for most impaired days at Mesa Verde National Park (MEVE1) for source category contributions to individual aerosol species. [TSS Modeling Express Tool](#) # 16.

11.0 State and Sector (Low-level) Source Apportionment

For the future year 2028OTBa2 model scenario, PSAT was applied to further define U.S. anthropogenic contributions to AmmNO₃ and AmmSO₄ aerosols at western Class I areas from each of 13 WESTAR-WRAP states and all other non-WRAP U.S. states combined. Methods are further detailed in the run specification sheet for [High-Level and Low-Level Source Apportionment Modeling](#) using the RepBase2 and 2028OTBa2 model scenarios (September 2020).

State contributions to AmmNO₃ and AmmSO₄ were subdivided into five anthropogenic source categories:

- electric generating units (EGU)
- oil and gas (area plus point sources) (OilGas)
- remaining point sources (non-EGU)
- Mobile onroad, nonroad, rail, and commercial marine vessels (CMV 1, 2, and 3 within 200 km of U.S. coast) (Mobile)
- remaining anthropogenic sources (including Fugitive dust, Agriculture, Agricultural fire, residential wood combustion, and all remaining nonpoint sources)

For each Class I area, these results identify which source sectors and states are projected to have the greatest contributions in 2028OTBa2 to visibility impairment due AmmSO₄ and AmmNO₃. These results can assist states to prioritize which emissions reductions strategies might be most effective in improving visibility at western Class I areas.

The state and sector source apportionment results in [TSS Modeling Express Tools](#) # 9 are absolute model outputs; results are not normalized to IMPROVE monitoring data. Users can choose to display state and sector source apportionment results for most impaired days (EPA default 2014 IMPROVE days), modeled most impaired days, or clearest days. This document provides examples for most impaired days only.

[TSS Modeling Express Tool](#) # 9 illustrated in **Figures 16a and 16b** for Yellowstone NP (YELL2) and **Figures 16c and 16d** for Mesa Verde NP (MEVE1), displays RepBase2 or 2028OTBa2 source apportionment results for western states and source sectors for AmmNO₃ or AmmSO₄ light extinction, respectively.

Interpretation: at YELL2 PSAT projects that AmmNO₃ contributions from individual states are 0.2 Mm⁻¹ or less. PSAT identifies mobile sources from several western states as the most important U.S. anthropogenic contributors to AmmNO₃ at YELL2 (**Figure 16a**). Idaho is shown as having the largest contributions to AmmNO₃ from mobile, non-EGU and area sources.

For AmmSO₄ at YELL2, PSAT projects that individual state contributions are small (0.15 Mm⁻¹ or less). Non-EGU, EGU, and area sources in several states are identified as contributors.

Figure 16a. 2028OTBa2 State and Sector Source Apportionment of Ammonium Nitrate Aerosol Light Extinction (Mm^{-1}) for most impaired days at the Yellowstone National Park (YELL2) IMPROVE monitor. [TSS Modeling Express Tool](#) # 9

Figure 16b. 2028OTBa2 State and Sector Source Apportionment of Ammonium Sulfate Aerosol Light Extinction (Mm^{-1}) for most impaired days at the Yellowstone National Park (YELL2) IMPROVE monitor. [TSS Modeling Express Tool](#) # 9

Figure 16c. 2028OTBa2 State and Sector Source Apportionment of Ammonium Nitrate Aerosol Light Extinction (Mm^{-1}) for most impaired days at the Mesa Verde National Park (MEVE1) IMPROVE monitor. [TSS Modeling Express Tool](#) # 9

Figure 16d. 2028OTBa2 State and Sector Source Apportionment of Ammonium Sulfate Aerosol Light Extinction (Mm^{-1}) for most impaired days at the Mesa Verde National Park (MEVE1) IMPROVE monitor. [TSS Modeling Express Tool](#) # 9

At MEVE1, AmmNO₃ contributions from individual states are 0.2 Mm⁻¹ or less. Oil and gas in NM, CO, and non-WRAP states are major contributors; oil and gas on tribal lands is included in the state contributions (see Table 3 in Section 3 of the [TSS Emissions Reference](#) document for breakdown of tribal vs non-tribal NO_x emissions.) EGU and mobile source sectors are also contributors to AmmNO₃. EGU from non-WRAP states and oil and gas in NM are the largest contributors to AmmSO₄ at MEVE1. [Weighted Emissions Potential](#) plots for MEVE1 confirm the Four Corners region and Arizona as the highest transport area for AmmNO₃ and that EGU in Texas contribute to AmmSO₄ loadings.

In general, at western Class I areas mobile emissions and oil and gas emissions are significant contributors to AmmNO₃, while electric generating units and remaining point sources are more important source categories for AmmSO₄.

12.0 Weighted Emissions Potential

WRAP 2028 [Weighted Emissions Potential](#) maps were developed to illustrate the geographic areas of greatest emissions influence for aerosol extinction on most impaired days at 76 IMPROVE monitors representing 116 Class I areas in the 13 WESTAR-WRAP states and neighboring states. 72-hour back trajectory analyses (defined every 6 hours for multiple start heights) for most impaired days for the 5-year period 2014-2018 were used to define frequency of atmospheric transport. Gridded 2028 modeled emissions in 36-km grid cells, residence time defined by back trajectory transport frequency, residence time weighted aerosol extinction for most impaired days (also called area of influence), and weighted emission potential for gridded emissions can be downloaded from the [Weighted Emissions Potential](#) webpage. The weighted emissions potential defines relative source importance for each Class I area. These analyses provide weight of evidence in support of state and sector source apportionment results in Section 11.0.

Figure 17a (left) displays the areas of highest influence from NO_x emissions, weighted by AmmNO₃ extinction on the most impaired days for YELL2, highlighted in burgundy and orange elliptical shapes overlaying eastern Idaho and western Wyoming. **Figure 17a (right)** displays the individual 36-km model grid cells, color graded by importance of mobile source NO_x emissions for AmmNO₃ extinction on most impaired days at YELL2 (burgundy, orange, and green grid cells have the highest importance). **Figure 17b (left)** displays areas of highest influence from SO₂ emissions, weighted by AmmSO₄ extinction on the most impaired days for YELL2.

Interpretation: The [Weighted Emissions Potential](#) maps agree with the PSAT results (Section 11.0) for YELL2 and MEVE1. For YELL2 the geographic area of influence is similar for AmmNO₃ and AmmSO₄ extinction (**Figures 17a, left and 17b, left.**) For mobile sources, the highest contributors to AmmNO₃ extinction on most impaired days at YELL2 include the mobile source corridors in Idaho and grid cells in Montana, Utah, Oregon and Washington (**Figure 17a, right**). Non-Electric generating point sources (non-EGU) in several states are seen as important

contributors to AmmSO₄ extinction on most impaired days at YELL2 (**Figure 17b right**). These results agree with PSAT results that identify mobile sources as largest contributors to AmmNO₃ (**Figure 16a**) and non-EGU point sources as largest contributors to AmmSO₄ extinction at YELL2 (**Figure 16b**).

Figure 17a. 2028OTBa2 Extinction Weighted Residence Time for Ammonium Nitrate (AmmNO₃) Light Extinction (Mm⁻¹) (left) and NO_x Weighted Emissions Potential for On-Road Mobile sources (right) for most impaired days at the Yellowstone National Park (YELL2) IMPROVE monitor. [Weighted Emissions Potential](#)

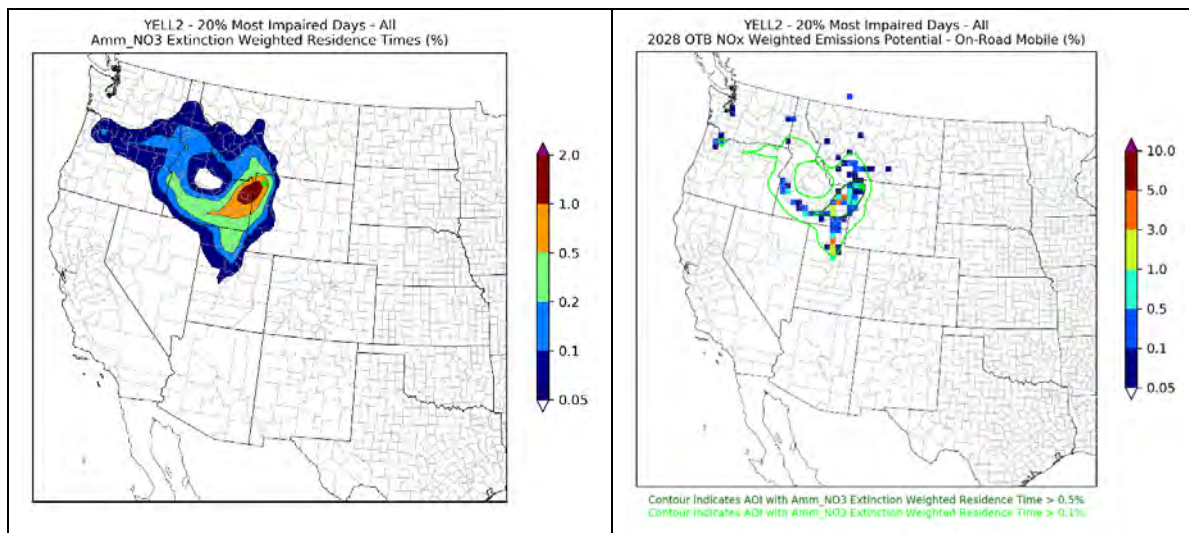

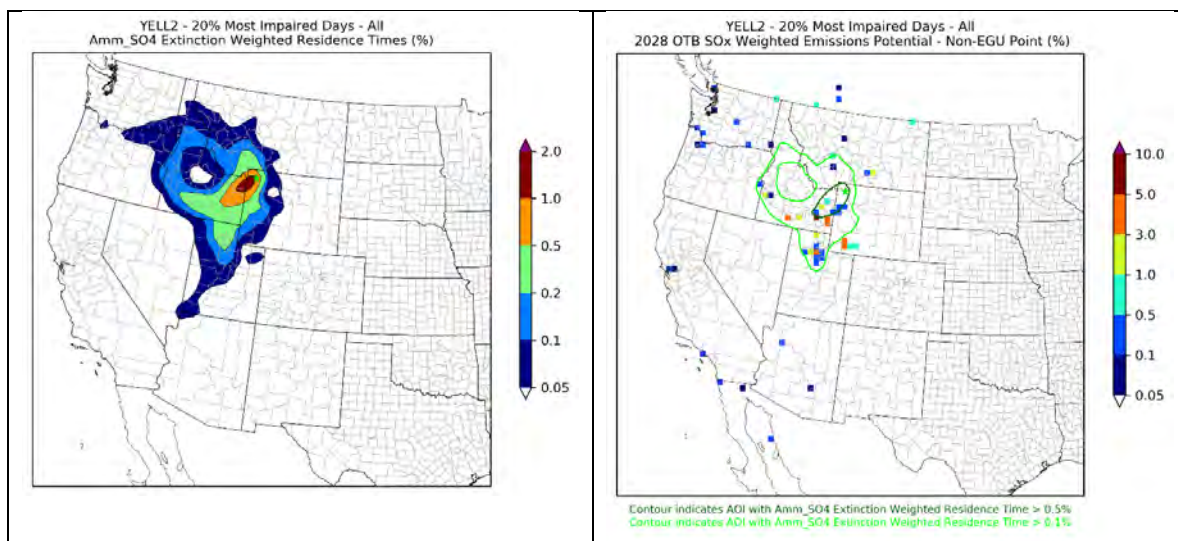

Figure 17b. 2028OTBa2 Extinction Weighted Residence Time for Ammonium Sulfate (AmmSO₄) Light Extinction (Mm⁻¹) (left) and SO₂ Weighted Emissions Potential for Non-Electric Generating Point sources (right) for most impaired days at the Yellowstone National Park (YELL2) IMPROVE monitor. [Weighted Emissions Potential](#)

For MEVE1, **Figure 17c, left** display the geographic areas of highest influence for NO_x emissions, weighted by AmmNO₃ extinction on the most impaired days. In **Figure 17c, right** the areas of highest influence are outlined in dark green and light green boundaries and oil and gas point and area sources contributions to AmmNO₃ are defined in color-graded 36-km grid cells. **Figure 17d, left** displays a very similar geographic area of influence for SO₂ emissions, weighted by AmmSO₄ extinction on most impaired days. **Figure 17d, right** illustrates that electric generating units that influence AmmSO₄ extinction at MEVE1 on most impaired days are geographically dispersed and not restricted to the geographic area of highest influence for total AmmSO₄.

Figure 17c. 2028OTBa2 Extinction Weighted Residence Time for Ammonium Nitrate (AmmNO₃) Light Extinction (Mm⁻¹) (left) and NO_x Weighted Emissions Potential for On-Road Mobile sources (right) for most impaired days at the Mesa Verde National Park (MEVE1) IMPROVE monitor. [Weighted Emissions Potential](#)

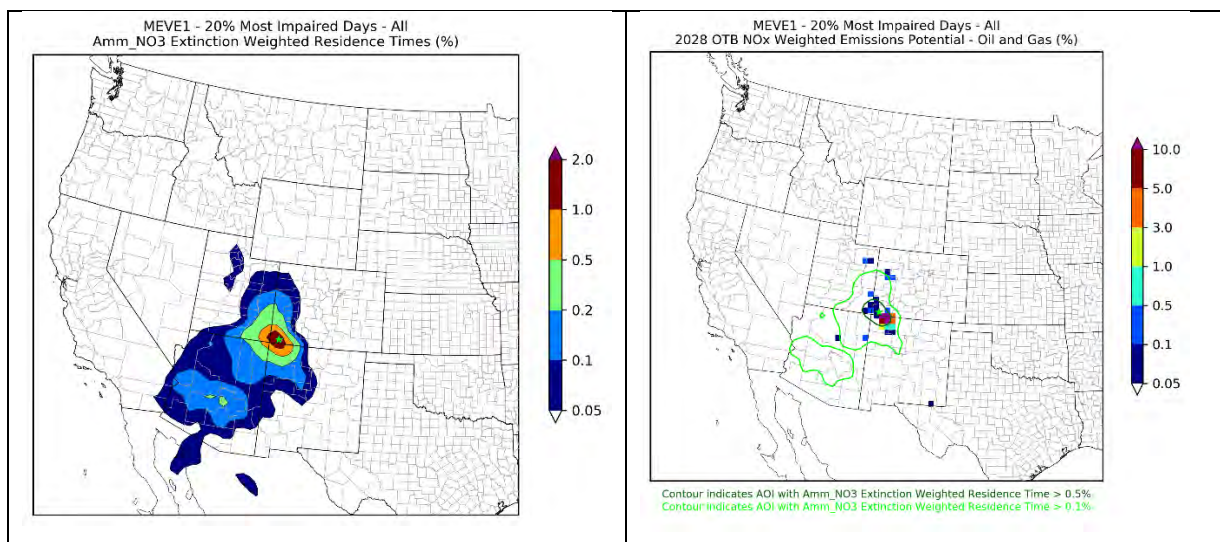

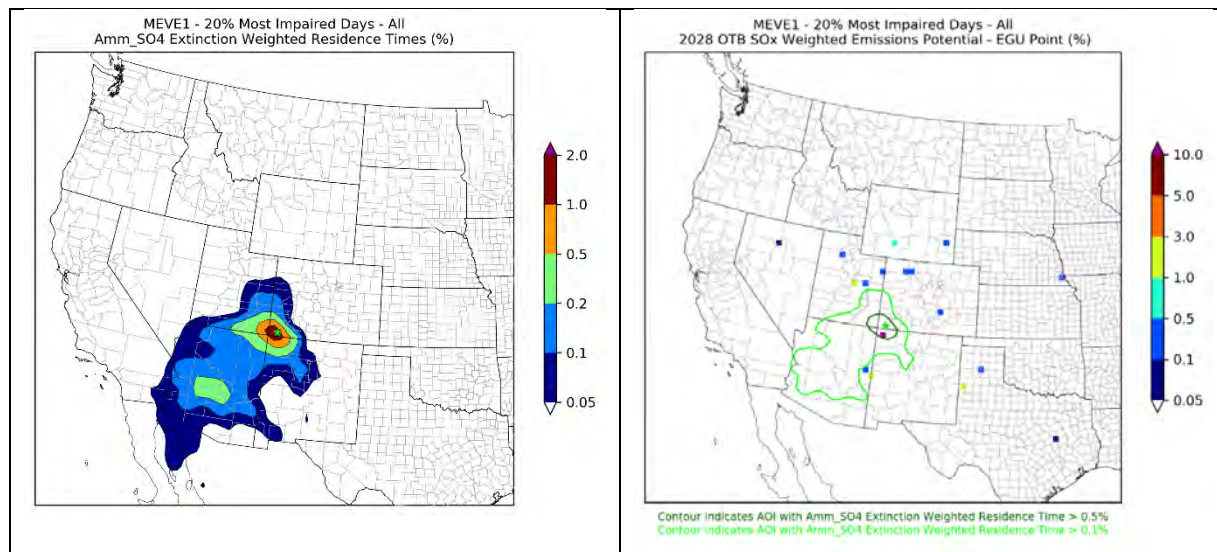

Figure 17d. 2028OTBa2 Extinction Weighted Residence Time for Ammonium Sulfate (AmmSO_4) light Extinction (Mm^{-1}) (left) and SO_2 Weighted Emissions Potential for Electric Generating Units (EGU) sources (right) for most impaired days at the Mesa Verde National Park (MEVE1) IMPROVE monitor. [Weighted Emissions Potential](#)

The area of greatest influence for AmmNO_3 extinction on most impaired days at MEVE1 (**Figure 17c, left**) is centered over the Four Corners area. In **Figure 17c, right** the area of greatest influence is outlined in the dark green elliptical boundary over the Four Corners and the lighter green boundary over portions of the four states: AZ, CO, NM, and UT. On the same plot, the 36-km grid cells are color coded by importance of NO_x emissions from oil and gas area and point sources. The oil and gas contributions are primarily located within the inner dark green area of influence.

The areas of greatest influence for AmmSO_4 extinction on most impaired days at MEVE1 are illustrated in **Figure 17d, left** and **17d, right**. The areas of influence are similar to those for AmmNO_3 extinction at MEVE1. The EGU plot illustrates emissions from elevated EGU point sources can influence visibility at a distant Class I area even if transport from the EGU point source is infrequent. These maps are consistent with the PSAT state and sector source apportionment for AmmNO_3 and AmmSO_4 at MEVE1 (Section 11.0)

13.0 Dynamic Model Evaluation

As part of the WRAP-WAQS 2014 modeling study, a dynamic model evaluation was conducted to test the model's ability to project changes in ambient aerosol visibility extinction at IMPROVE monitoring sites in response to changes in U.S. anthropogenic emissions. To conduct the dynamic model evaluation, in addition to the 2014v2, RepBase2 and 2028OTBa2 model

scenarios already discussed, an additional scenario representing U.S. anthropogenic emissions for 2002 (2002 Hindcast) was run using the CAMx-PSAT photochemical grid model platform with 2014 meteorology and RepBase2 emissions for all other natural, fire, and international source groups. Only U.S. anthropogenic emissions changed between the 2002 Hindcast, RepBase2, and 2028OTBa2 model scenarios. 2002 U.S. Anthropogenic emissions were back cast from the 2014 National Emissions Inventory (NEI) using scaling factors based on EPA's NEI trends for most sectors, with exceptions that California Air Resources Board provided 2014 to 2002 scaling factors for California, and western states supplied 2002 emissions for point sources (electric generating units (EGU), oil and gas point sources, and other non-EGU point sources.) Methods for the 2002 Hindcast are further defined in the [U.S. Anthropogenic Emissions Rate of Progress](#) document (September 2021).

The dynamic model evaluation applied the same future year projection methods defined by Environmental Protection Agency [modeling guidance](#) (December 2018) to project 2014-2018 visibility from the 2002 Hindcast forward to the RepBase2 scenario. Relative response factors for each aerosol species were calculated (RepBase2 model results divided by 2002 Hindcast model results) and then multiplied by 2000-2004 IMPROVE observations for each species to project RepBase2 visibility. Model projected RepBase2 aerosol light extinction closely matched IMPROVE observed light extinction for 2014-2018 5-year average (**Figure 18a**). This confirmation increases confidence that the CAMx model and EPA projection methods can produce credible 2028 visibility projections. Backward projections of 2002 visibility from RepBase2 (relative response factors calculated as 2002 Hindcast divided by RepBase2 and then multiplied by 2014-2018 IMPROVE observations) had larger discrepancies from 2000-2004 IMPROVE observations than forward projections from 2002 to RepBase2, but still showed good agreement for most western IMPROVE sites (**Figure 18b**). The larger discrepancies for the 2002 Hindcast are likely due to a combination of (i) using RepBase2 levels of fire and international emissions for the 2002 Hindcast model run that differed from the actual emissions that contributed to 2000-2004 IMPROVE observations and (ii) using scaling factors to calculate 2002 Hindcast emissions from 2014v2 National Emissions Inventory that introduces errors for U.S. anthropogenic emissions (e.g., over estimating 2002 emissions for Commercial Marine Vessel emissions). A future dynamic model evaluation may want to back cast natural, fire and international emissions as well as U.S. anthropogenic emissions.

Figure 18a. Dynamic Model Evaluation applying EPA projection methods and comparing total aerosol light extinction for 2014-2018 IMPROVE observations (x-axis) to modeled RepBase2 (y-axis) for Class I areas in the 13 western states. [U.S. Anthropogenic Emissions Rate of Progress](#)

Figure 18b. Dynamic Model Evaluation applying EPA projection methods and comparing total aerosol light extinction for 2000-2004 IMPROVE observations (x-axis) to modeled 2002 Hindcast (y-axis) for Class I areas in the 13 western states. [U.S. Anthropogenic Emissions Rate of Progress](#)

14.0 U.S. Anthropogenic Emissions Rate of Progress

WRAP has defined a U.S. Anthropogenic Emissions Rate of Progress to demonstrate visibility progress at western Class I areas due to changes in U.S. Anthropogenic emissions between the 2002 Hindcast, RepBase2, and 2028OTBa2 model scenarios. Methods for the 2002 Hindcast, RepBase2 and 2028OTBa2 scenario development are further defined in the WRAP-WAQS run specification sheets

- [Representative Baseline v2 and 2028OTBa2](#)
- [U.S. Anthropogenic Emissions Rate of Progress](#)

The URP glidepath represents total haze from all source contributions on most impaired days. In the western U.S., haze is caused by international, natural, and fire emissions as well as U.S. anthropogenic emissions. Uncertainties in the URP glidepath construction are further described in the [U.S. Anthropogenic Emissions Rate of Progress](#) webpage.

The objective of the U.S. Anthropogenic Emissions Rate of Progress is to isolate the contributions of U.S. anthropogenic emissions to visibility at Class I areas in the WESTAR-WRAP states and to demonstrate the progress in improving visibility in response to changes in U.S. anthropogenic emissions between the 2002 Hindcast, RepBase2, and 2028OTBa2 scenarios.

- Only U.S. anthropogenic emissions change in the three model scenarios.
 - Any differences in aerosol extinction between the 2002, RepBase2, and 2028OTBa2 scenarios are due to changes in U.S. anthropogenic emissions.
 - We have greatest confidence in U.S. anthropogenic emissions.
- All other emissions (natural, fire, and international) are held constant at RepBase2 levels for the 2002 Hindcast and 2028OTBa2 scenarios.
 - Because RepBase2 international, fire, and natural emissions are used in the 2002 Hindcast scenario, the 2002 Hindcast results are not fully comparable to the 2000-2004 IMPROVE monitoring data.
- The source apportionment model results are not adjusted to the IMPROVE monitoring data.
- The U.S. Anthropogenic Emissions Rate of Progress is intended as an alternative to adjusting the 2064 endpoint of the URP glidepath using 2028 source apportionment results for international and U.S. wildland prescribed fire, per EPA guidance.

[TSS Modeling Express Tool](#) # 6, illustrated in **Figures 19a and 19b** displays US Anthropogenic, International Anthropogenic, Natural, Fire, and Rayleigh contributions to total light extinction for the 2002 Hindcast, RepBase2, and 2028OTBa2 model scenarios for the IMPROVE monitors at Yellowstone (YELL2) and Mesa Verde (MEVE1) National Parks, respectively.

Interpretation: at YELL2 U.S. Anthropogenic contributions are projected to be reduced by 2 Mm^{-1} (39%) between 2002 Hindcast and RepBase2 and by 1 Mm^{-1} (30%) between RepBase2 and 2028OTBa2. This rate of progress is below the straight line drawn from 2002 U.S. anthropogenic contribution to zero U.S. anthropogenic contribution in 2064. This is in contrast to conclusions following EPA guidance, where 2028OTBa2 visibility projections for YELL2 are not below the URP glidepath (Section 8.0). The modeled rate of U.S. anthropogenic progress is below the glidepath to no U.S. anthropogenic contribution.

At MEVE1, U.S. anthropogenic contributions are projected to be reduced by 3 Mm^{-1} (41%) between 2002 Hindcast and RepBase2 and by 0.8 Mm^{-1} (18%) between RepBase2 and 2028OTBa2. This rate of progress is below the straight line drawn from 2002 U.S. anthropogenic contribution to zero U.S. anthropogenic contribution in 2064.

Figure 19a. Contributions to Aerosol Light Extinction from U.S. Anthropogenic, International Anthropogenic, Natural, and Fire emissions, plus Rayleigh light scattering, for the 2002 Hindcast, RepBase2, and 2028OTBa2 model scenarios for most impaired days at Yellowstone National Park (YELL2) IMPROVE monitor. [TSS Modeling Express Tool](#) # 6

Figure 19b. Contributions to Aerosol Light Extinction from U.S. Anthropogenic, International Anthropogenic, Natural, and Fire emissions, plus Rayleigh light scattering, for the 2002 Hindcast, RepBase2, and 2028OTBa2 model scenarios for most impaired days at Mesa Verde National Park (MEVE1) IMPROVE monitor. [TSS Modeling Express Tool](#) # 6

[TSS Modeling Express Tool](#) # 7, illustrated in **Figures 20a and 20b** displays aerosol species contributions to just the U.S. Anthropogenic fraction of total light extinction for the 2002 Hindcast, RepBase2 and 2028OTBa2 model scenarios for the IMPROVE monitors at Yellowstone (YELL2) and Mesa Verde (MEVE1) National Parks, respectively.

- TSS Chart 7 does not address aerosol light extinction from sources other than U.S. Anthropogenic contributions.
- The source apportionment model results are not adjusted to the IMPROVE monitoring data.

Interpretation: at both YELL2 and MEVE1, reductions in U.S. anthropogenic contributions between 2002 Hindcast and RepBase2 are primarily due to reductions in AmmSO₄ and OMC. At YELL2, reductions projected to occur between RepBase2 and 2028OTBa2 are primarily due to reductions in AmmNO₃. At MEVE1, reductions in U.S. anthropogenic contributions between RepBase2 and 2028OTBa2 are projected due to small reductions in AmmNO₃ and AmmSO₄.

Figure 20a. U.S. Anthropogenic Contributions to Speciated Aerosol Light Extinction for the 2002 Hindcast, RepBase2, and 2028OTBa2 model scenarios for most impaired days at Yellowstone National Park (YELL2) IMPROVE monitor. [TSS Modeling Express Tool](#) # 7

Figure 20b. 2028 U.S. Anthropogenic Contributions to Speciated Aerosol Light Extinction for the 2002 Hindcast, RepBase2, and 2028OTBa2 model scenarios for most impaired days at Mesa Verde National Park (MEVE1) IMPROVE monitor. [TSS Modeling Express Tool](#) # 7

15.0 Future Fire Sensitivities

Future fire sensitivities added wildfire emissions (FFS1) or wildland prescribed fire emissions (FFS2) as two potential future variations in fire activity that are not specific to any single future year. The fire sensitivities are added to the 2028OTBa2 reference case scenario to replace historic fire emissions used in the RepBase2 and 2028OTBa2 scenarios. All other 2028OTBa2 emissions: U.S. anthropogenic, international, natural, and non-US fire emissions are held constant. The only differences between the 2028OTBa2 and the fire sensitivities are due to the FFS1 and FFS2 assumptions.

- **FFS1** examines the effects of potential future changes in the timing, frequency, and intensity in terms of acres burned for **wildfires** compared to the Representative Baseline fires.
- **FFS2** examines the effects of potential future enhanced forest management practices defined as increases in **wildland prescribed burns**.

Emissions development of the future fire sensitivities is described in the Air Sciences, Inc. report [Fire Emissions Inventories for Regional Haze Planning: Methods and Results](#) (April 2020).

Modeling procedures are detailed in the run specification sheet for the [Future Fire Simulations](#) (August 2021).

[TSS Modeling Express Tool](#) # 18, illustrated in **Figures 21a and 21b**, displays IMPROVE 2014-2018 aerosol light extinction (Mm^{-1}) compared to the 2028 visibility projections for the 2028OTBa2, Future Wildfire Sensitivity, and Future Wildland Prescribed Fire Sensitivity scenarios for the IMPROVE monitors at Yellowstone (YELL2) and Mesa Verde (MEVE1) National Parks, respectively.

In [TSS Modeling Express Tool](#) # 18, fire sensitivities have been processed through the EPA Software for Modeled Attainment Test (normalized to IMPROVE 2014-2018 observations) to test the impact of changing fire regimes on 2028 regional haze visibility projections. The fire sensitivities for wildfire and wildland prescribed fire are compared to the 2028OTBa2 visibility projections for most impaired days or clearest days.

Interpretation: Added fire activity does not necessarily occur on 2014 IMPROVE most impaired days. The impacts of changing fire activity on the regional haze metrics are site-specific and may be small. IMPROVE 2014-2018 observations are included in TSS Modeling Express Tool #18 as the baseline data used with the relative response factors to calculate the 2028 visibility projections. At YELL2 (**Figure 21a**), the 2028OTBa2 visibility projection shows small decreases in AmmNO_3 , OMC, and EC compared to 2014-2018 observations. The Future Wildfire Sensitivity and the Future Wildland Prescribed fire sensitivity show minor increases in OMC that can be attributed to changes in fire activity on some most impaired days in these sensitivities.

Figure 21a. IMPROVE 2014-2018 aerosol light extinction (Mm^{-1}) compared to the 2028 visibility projections (following EPA guidance) for the 2028OTBa2, Future Wildfire Sensitivity, and Future Wildland Prescribed Fire Sensitivity scenarios for most impaired days at the Yellowstone National Park (YELL2) IMPROVE monitor. [TSS Modeling Express Tool](#) # 18

At MEVE1 (**Figure 21b**), OMC is a smaller contributor on most impaired days than at YELL2. 2028OTBa2 visibility projection shows small decreases in AmmSO4 and AmmNO3 compared to the 2014-2018 IMPROVE observations. OMC increases in the Future Wildfire sensitivity indicating increased fire emissions on some most impaired days for this sensitivity. OMC is little changed in the Future Wildland Prescribed fire sensitivity compared to 2028OTBa2.

Figure 21b. IMPROVE 2014-2018 aerosol light extinction (Mm^{-1}) compared to the 2028 visibility projections (following EPA guidance) for the 2028OTBa2, Future Wildfire Sensitivity, and Future Wildland Prescribed Fire Sensitivity scenarios for most impaired days at the Mesa Verde National Park (MEVE1) IMPROVE monitor. [TSS Modeling Express Tool](#) # 18

[TSS Modeling Express Tool](#) # 19, illustrated in **Figures 22a and 22b**, displays absolute model results (not adjusted to IMPROVE observations) for 2028OTBa2 and the future fire sensitivities as monthly averages for all IMPROVE sample collection days. This chart illustrates when changes in wildfire or wildland prescribed fire activity are projected to occur and how the changes affect visibility compared to the 2028OTBa2 fire assumptions. These results are not 2028 visibility projections (adjusted to IMPROVE data) for regional haze planning purposes.

Interpretation: at YELL2 (**Figure 22a**) in several months there are small differences in AmmSO₄, AmmNO₃, and OMC between the 2028OTBa2 scenario and the Future Fire Sensitivities. The Future Wildfire Sensitivity is higher than 2028OTBa2 in July, September and October, while the Future Wildland Prescribed Fire Sensitivity is higher in January, February, April, May, October, and November. Not all the fire activity changes occurred on most impaired days so the impacts on the 2028 visibility projections are small.

Figure 22a. Monthly average aerosol extinction (Mm^{-1}) for the 2028OTBa2, Future Wildfire Sensitivity, and Future Wildland Prescribed Fire Sensitivity scenarios for most impaired days at the Yellowstone National Park (YELL2) IMPROVE monitor. [TSS Modeling Express Tool](#) # 19

Figure 22b. Monthly average aerosol extinction (Mm^{-1}) for the 2028OTBa2, Future Wildfire Sensitivity, and Future Wildland Prescribed Fire Sensitivity scenarios for most impaired days at the Mesa Verde National Park (MEVE1) IMPROVE monitor. [TSS Modeling Express Tool](#) # 19

At MEVE1 (**Figure 22b**) the Future Wildfire Sensitivity shows very slight monthly differences compared to the 2028OTBa2 scenario, even though the Future Wildfire visibility projection has slightly higher OMC than the 2028OTBa2 projection (**Figure 21b**). This suggests that wildfire activity added on a few most impaired days was offset by decreased wildfire activity on other days in the monthly averages. The Future Wildland Prescribed Fire Sensitivity in June and November show slightly higher OMC than 2028OTBa2, but little change in the 2028 visibility projection.

At some western Class I areas, the added future fire sensitivities have larger impacts than seen as these two sites. Fires will continue to be a major contributor to haze in western states, however the regional haze tracking metric may not be the best measure of changes in future fire activity.

16.0 Modeling Data files

Raw modeling data files can be downloaded from the TSS Modeling Express Tools #22-25 as illustrated below. Data are sorted by geographic area, by IMPROVE data groups, Model scenarios, pollutant parameters, and regional haze projection methods. Data can be downloaded as ASCII text, Microsoft Excel, or JSON format.

Appendix D – FLM Consultation and Public Record
D.1 – Notice of Opportunity for Early Consultation

Stroh, David E.

From: Stroh, David E.
Sent: Wednesday, September 15, 2021 10:03 AM
To: Pohlman, David C.; King, Kirsten L; Peters, Melanie; Shepherd, Don
Cc: Thorton, Rhannon T.; Semerad, Jim L.
Subject: North Dakota - DRAFT Regional Haze SIP for Consultation
Attachments: 20210915_NationalParkService Ltr.pdf

David, Kirsten, Melanie, Don,

Attached is a signed electronic notice for the North Dakota Department of Environmental Quality (NDDEQ) DRAFT regional haze state implementation plan (RH SIP) revision. This plan is being made available to provide you with an early opportunity to comment on NDDEQ's current DRAFT RH SIP Revision.

The location of the material available for review is included in the attached notice and can be found at:

<https://www.deq.nd.gov/AQ/planning/RegHaze.aspx>

(note: webpage and material will be updated prior to Sept. 20th)

Comments can be sent through the mail or electronically to: AirQuality@nd.gov

If electronic comments are provided, please include "Regional Haze Consultation Comments" in the subject line.

Please review the attached and reach out with any comments or questions. We look forward to engaging with you in the next steps of the regional haze process.

Regards,

David

David Stroh

Sent via Email to david_pohlman@nps.gov, kirsten_king@nps.gov, melanie_peters@nps.gov and Don_Shepherd@nps.gov

David Pohlman, Kirsten King, Melanie Peters, and Don Sheperd:

In accordance with provisions of the federal Regional Haze Rule (RHR) under 40 Code of Federal Regulations, Part 51, Subpart P, §51.308(i)(2), the State of North Dakota is hereby offering the opportunity for consultation on the draft Regional Haze State Implementation Plan (RH SIP) revision.

The draft RH SIP revision has been uploaded to the North Dakota Department of Environmental Quality, Division of Air Quality's Regional Haze webpage:

<https://www.deq.nd.gov/AQ/planning/RegHaze.aspx>

A 60-day consultation period for North Dakota's draft RH SIP revision will be held from September 20, 2021 through November 19, 2021. Written comments can be mailed to the North Dakota Department of Environmental Quality, Division of Air Quality, 4201 Normandy Street, Bismarck, ND 58503-1324 or emailed to AirQuality@nd.gov. Comments sent via email should include "Regional Haze Consultation Comments" in the subject line.

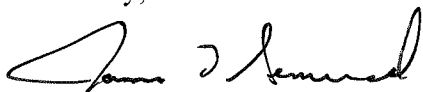

Upon completion of the consultation period, North Dakota will include a description of how comments provided by the appropriate stakeholders were addressed. Only comments received from appropriate stakeholders will be added during this consultation period.

If you are unable to access the draft RH SIP revision online, require a hardcopy or prefer the information through other means, contact David Stroh at (701)328-5229 or destroh@nd.gov.

If you wish to schedule an in-person or video conference meeting to discuss the draft RH SIP revision, contact David Stroh.

If you have any general questions about this process, please contact David Stroh or myself at (701)328-5188.

Sincerely,

Jim Semerad
Director
Division of Air Quality

Aaron and Jaslyn,

Attached is a signed electronic notice for the North Dakota Department of Environmental Quality (NDDEQ) DRAFT regional haze state implementation plan (RH SIP) revision. This plan is being made available to provide you with an early opportunity to comment on NDDEQ's current DRAFT RH SIP Revision.

The location of the material available for review is included in the attached notice and can be found at:

<https://www.deq.nd.gov/AQ/planning/RegHaze.aspx>

(note: webpage and material will be updated prior to Sept. 20th)

Comments can be sent through the mail or electronically to: AirQuality@nd.gov

If electronic comments are provided, please include "Regional Haze Consultation Comments" in the subject line.

Please review the attached and reach out with any comments or questions. We look forward to engaging with you in the next steps of the regional haze process.

Regards,

David

Sent via Email to Worstell.Aaron@epa.gov and Dobrahner.Jaslyn@epa.gov

Aaron Worstell and Jaslyn Dobrahner:

In accordance with provisions of the federal Regional Haze Rule (RHR) under 40 Code of Federal Regulations, Part 51, Subpart P, §51.308(i)(2), the State of North Dakota is hereby offering the opportunity for consultation on the draft Regional Haze State Implementation Plan (RH SIP) revision.

The draft RH SIP revision has been uploaded to the North Dakota Department of Environmental Quality, Division of Air Quality's Regional Haze webpage:

<https://www.deq.nd.gov/AQ/planning/RegHaze.aspx>

A 60-day consultation period for North Dakota's draft RH SIP revision will be held from September 20, 2021 through November 19, 2021. Written comments can be mailed to the North Dakota Department of Environmental Quality, Division of Air Quality, 4201 Normandy Street, Bismarck, ND 58503-1324 or emailed to AirQuality@nd.gov. Comments sent via email should include "Regional Haze Consultation Comments" in the subject line.

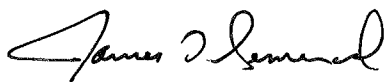

Upon completion of the consultation period, North Dakota will include a description of how comments provided by the appropriate stakeholders were addressed. Only comments received from appropriate stakeholders will be added during this consultation period.

If you are unable to access the draft RH SIP revision online, require a hardcopy or prefer the information through other means, contact David Stroh at (701)328-5229 or destroh@nd.gov.

If you wish to schedule an in-person or video conference meeting to discuss the draft RH SIP revision, contact David Stroh.

If you have any general questions about this process, please contact David Stroh or myself at (701)328-5188.

Sincerely,

Jim Semerad
Director

September 16, 2021

Nathan Davis, Director
North Dakota Indian Affairs Commission
Sent via email only to nathan.davis@nd.gov

Dear Mr. Davis:

The North Dakota Department of Environmental Quality (NDDEQ), Division of Air Quality recently completed a draft Regional Haze State Implementation Plan (RH SIP) revision. This draft RH SIP revision is required under 40 CFR Part 51, Subpart P, §51.308 (<https://www.ecfr.gov/current/title-40/chapter-I/subchapter-C/part-51/subpart-P/section-51.308>).

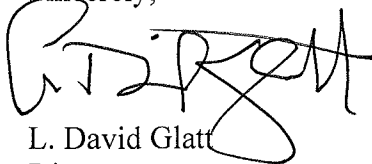

As part of NDDEQ's coordination efforts, we have made the draft RH SIP revision available for review and comment to our tribal partners at: <https://www.deq.nd.gov/AQ/planning/RegHaze.aspx>

The review/comment period is set to run from September 20, 2021, through November 19, 2021.

We wanted to make you aware of the outreach NDDEQ has made toward this effort in the event you receive questions/comments on the matter. I have attached the letters sent to our tribal partners (the Mandan, Hidatsa and Arikara Nation; the Standing Rock Sioux; the Turtle Mountain Band of Chippewa; the Sisseton Wahpeton Oyate; and the Spirit Lake Nation) offering the opportunity for consultation with NDDEQ on this draft RH SIP revision.

Should you receive feedback from any of our tribal partners regarding this matter and/or if there is a desire to schedule an in-person or teleconference meeting to review the draft RH SIP revision, please reach out to David Stroh at destroh@nd.gov or 701-328-5229 to coordinate.

Sincerely,

L. David Glatt

Morning David,

We have received the comments. I was also able to access the calculation spreadsheets (the zip files) from the Sharepoint link provided by Sara Wilson (folder name: "NPS-ND_RH_Calculations_And_References").

If we have any questions/comments as we work through these documents, we will reach out.

Thank you,

David

David,

I tried sending out consultation comments to ND, but I got an "undeliverable" message from all the ND addressees. I'm sending it again without the .zip file which seems to be problematic. Any ideas on how to get that file to you? It contains all the calculations spreadsheets, etc.

Have a good weekend!

Subject: NPS Consultation on Draft North Dakota Regional Haze SIP

Hello David,

The National Park Service (NPS) appreciates the opportunity to review the Federal Land Manager (FLM) review draft of the North Dakota Regional Haze State Implementation Plan (SIP) for the Second Implementation Period (2018-2028). On October 19, 2021, staff from the NPS Air Resources Division (ARD) and NPS Interior Regions 3, 4, and 5 hosted a regional haze consultation meeting with the North Dakota Department of Environmental Quality (NDDEQ) staff to discuss NPS input on the draft North Dakota Regional Haze SIP. Representatives from the U.S. Forest Service and Environmental Protection Agency (Region 8) also attended. An annotated set of slides shared during this meeting are attached along with detailed technical feedback and supporting calculation worksheets. This email and the attachments document NPS conclusions and recommendations presented during our formal regional haze consultation, as required by 42 U.S.C. §7491(d).

As you know, North Dakota contains one NPS managed Class I area, Theodore Roosevelt National Park. Of all states North Dakota has the biggest influence on haze in NPS Class I areas based on a cumulative analysis of surrogate visibility impacts (emissions/distance). Emissions from North Dakota point and area sources are significant across the region and specifically contribute to regional haze at Theodore Roosevelt National Park in North Dakota as well as Badlands and Wind Cave National Parks in South Dakota.

We recognize North Dakota for putting together a well laid out and detailed SIP, and for engaging with NPS early in the SIP development process. We appreciate your commitment to reducing pollutants in the region to help improve visibility in all Class I areas. Still, significant additional progress is necessary before the ultimate visibility goal of no human caused visibility impairment is realized. It is with this in mind that we provide SIP review feedback, summarized here.

North Dakota selected all of the NPS recommended facilities to analyze for haze causing emission reduction opportunities. The North Dakota draft SIP provides some of the best four-factor analyses that we have reviewed in this planning period. However, there are several overarching issues that generally inflated costs associated with controls. Please see the attached technical review document and supporting calculation worksheets for a detailed review of individual analyses.

As part of early engagement, NPS requested that North Dakota consider opportunities to reduce haze causing emissions from the oil and gas sector. NPS research indicates that oil and gas emissions contribute to visibility impairment at Theodore Roosevelt National Park. Emissions from oil and gas sources in the North Dakota portion of the Williston Basin are the highest in the Western Regional Air Partnership region, and are projected to increase rather than decrease. However, North Dakota determined individual engine controls are not reasonable during this planning period. Significant cumulative emissions coupled with a limited footprint from any single wellsite points to the need for statewide rules addressing the oil and gas source sector. Many states now implement state or region-wide requirements to limit NOx emissions from area source engines. We encourage North Dakota to consider similar rules to reduce haze causing emissions in this planning period.

We request that North Dakota remove the discussion of correlation between most visually impaired days at Theodore Roosevelt National Park and park visitation.

We recommend that North Dakota establish a cost-effectiveness threshold for reasonable progress in line with other states and/or based on North Dakota thresholds used for previous rounds of regional haze (adjusted for inflation). In doing so, the four-factor analyses would likely show that a number of cost-effective controls are available for the facilities evaluated.

In the draft SIP NDDEQ concludes that additional measures are not needed because:

- Trends in haze on most impaired days are going down.
- Progress on most impaired days is below adjusted uniform rate of progress (URP).
- They will not result in significant visibility improvements.

While overall visibility impairment trends are improving, in recent years (2016-2019) haze has increased on the most impaired days in NPS Class I areas most affected by North Dakota emissions. Continuous improvement will be needed to continue the downward trend in haze and meet the 2064 goals. The URP glideslope is a planning tool, not a standard. EPA has made it clear that being under the glideslope is not a reason to dismiss otherwise reasonable controls. The goal of the Clean Air Act and the Regional Haze Rule is natural conditions, and no Class I area in the state or downstream has reached that goal yet.

Visibility improvement in Class I areas depends on the cumulative effects of regional emission reductions. Although the EPA 2019 Regional Haze Guidance allows states to consider visibility when determining their long-term strategy, the guidance did not intend for visibility improvement to be used as a fifth factor to reject controls that would otherwise be determined reasonable. In order to achieve reasonable progress in this round of SIP development we request that North Dakota require all technically feasible and cost-effective controls identified through four-factor analysis.

Please know that we welcome the opportunity for further dialogue with you as North Dakota progresses to a final SIP revision. If you have any questions, do not hesitate to reach out to us. Also, feel free to let us know if you have any edits to this summary and especially if any corrections are needed.

Best,

David

1 Executive Summary

The National Park Service (NPS) appreciates the opportunity to review the Federal Land Manager (FLM) review draft of the North Dakota Regional Haze State Implementation Plan (SIP) for the Second Implementation Period (2018-2028). On October 19, 2021, staff from the NPS Air Resources Division (ARD) and NPS Interior Regions 3, 4, and 5 hosted a regional haze consultation meeting with the North Dakota Department of Environmental Quality (NDDEQ) staff to discuss NPS input on the draft North Dakota Regional Haze SIP. We provide the following recommendations to strengthen the SIP, which were discussed during our consultation meeting and detailed in this document.

North Dakota is home to one NPS-managed Class I area, Theodore Roosevelt National Park. Of all states, North Dakota has the most significant influence on haze in NPS Class I areas based on a cumulative analysis of surrogate visibility impacts (emissions/distance). Emissions from North Dakota point and area sources contribute to regional haze at Theodore Roosevelt National Park in North Dakota as well as Badlands and Wind Cave National Parks in South Dakota.

In summary, we request that North Dakota:

1. Require cost-effective measures to reduce haze-forming pollutants identified through the four-factor analyses in SIP. Our facility-specific recommendations are discussed in subsequent sections.
2. Consider oil and gas emission reduction opportunities in this planning period.
3. Establish a cost-effectiveness threshold for reasonable progress that is in line with other states and/or based on NDDEQ thresholds used for previous rounds of regional haze (adjusted for inflation) (see Section 2.2).
4. Remove the discussion that correlates the most visually impaired days at Theodore Roosevelt National Park with park visitation data (see Section 2.1).

In the draft SIP NDDEQ concludes that additional emission reduction measures are not needed because:

- Trends in haze on most impaired days are going down.
- Progress on most impaired days is below the adjusted uniform rate of progress (URP).
- They will not result in significant visibility improvements.

While overall visibility impairment trends are improving, in recent years (2016-2019) haze has increased on the most impaired days in NPS Class I areas most affected by North Dakota emissions. Continuous improvement will be needed to continue the downward trend in haze and meet the 2064 goals. The URP glideslope is a planning tool, not a standard. EPA has made it clear that being under the glideslope is not a reason to dismiss otherwise reasonable controls. The goal of the Clean Air Act and the Regional Haze Rule is natural conditions, and no Class I area in the state or downstream has reached that goal (see Section 2.3).

Visibility improvement in Class I areas depends on the cumulative effects of regional emission reductions. Although the EPA 2019 Regional Haze Guidance allows states to consider visibility

when determining their long-term strategy, the guidance did not intend for visibility improvement to be used as a fifth factor to reject otherwise reasonable controls. To achieve reasonable progress in this round of SIP development we request that North Dakota require technically feasible and cost-effective controls identified through the four-factor analyses (see Section 2.3).

NDDEQ selected all the NPS recommended facilities to analyze for haze causing emission reduction opportunities. Four-factor reasonable progress analyses for the following facilities are included in the North Dakota draft SIP:

- Coyote Station
- Antelope Valley Station
- Coal Creek Station
- Milton R Young Station
- Leland Olds Station
- R M Heskett Station
- Great Plains Synfuels Plant
- Tioga Gas Plant
- Little Knife Gas Plant
- Northern Border Pipeline Compressor Station No. 4

The North Dakota draft SIP provides some of the best, technically sound four-factor analyses that the NPS has reviewed in this planning period. However, there are several recurring issues with the four-factor analyses that generally the inflated cost of controls. These are discussed in Section 2.4 of this document. The potential to use Selective Catalytic Reduction (SCR) to reduce nitrogen oxide emission for units burning North Dakota lignite coal is evaluated and discussed in Section 2.5. Please see Section 3 and supporting calculation worksheets for a detailed review of individual four-factor analyses.

As part of early engagement, NPS requested that NDDEQ consider opportunities to reduce haze causing emissions from the upstream oil and gas source sector. As described in Section 4, NPS research indicates that oil and gas emissions contribute to visibility impairment at Theodore Roosevelt National Park. NO_x emissions from oil and gas sources in the North Dakota portion of the Williston Basin are the highest in the Western Regional Air Partnership region. Modest decreases in NO_x emissions are projected for North Dakota oil and gas sources, while SO₂ emissions are projected to increase by 2028. However, NDDEQ determined individual engine controls are not reasonable during this planning period. Significant cumulative emissions coupled with a limited footprint from any single wellsite points to the need for statewide rules addressing the oil and gas source sector. Many states now implement state or region-wide requirements to limit NO_x emissions from engines. We encourage NDDEQ to consider similar rules to reduce haze causing emissions in this planning period.

2 Overarching feedback

2.1 Low visitation correlation with most impaired days

In section 1.3.2 of the SIP, NDDEQ noted that 75% of visitation to Theodore Roosevelt NP occurs during the months of June through September, but that these four months account for only 4% of the most impaired days. From this, the SIP concludes that “that focusing on the MID for TRNP will not meaningfully improve visibility or a visitor’s experience in TRNP” (p. 25). We disagree with this conclusion for the following reasons. First, the Clean Air Act amendments of 1977 set a national goal of the “prevention of any future, and the remedying of any existing, impairment of visibility in mandatory Class I federal areas which impairment results from man-made air pollution.” In order to meet this goal, the Clean Air Act requires that the long-term strategy and reasonable progress goals must provide for improvement in visibility on the most impaired days while preventing deterioration of visibility on the clearest days and that reasonable progress determinations are to be based on the four statutory factors. In its 2019 guidance document (*Guidance on Regional Haze State Implementation Plans for the Second Implementation Period*, August 2019), EPA also addressed this issue by saying (p. 41):

We do not recommend the use of weighting of visitation, high or low, in protecting visibility in Class I areas. In addition, we believe that a state should not give less weight to protecting visibility in a given Class I area during times of the year with lower visitation.

Second, while park visitation is higher in the summer months, that should not discount the importance of the visitor experience in other months of the year. The National Park Service’s Organic Act (16 U.S.C. §1) requires the service to conserve resources “in a manner and by such means as will leave them unimpaired” for future generations. The Act does not allow the service to provide less protection for park resources based upon the timing or relative levels of visitation. In 2021, there were 115,884 visitors to Theodore Roosevelt NP in January through May.¹ Visitor survey data consistently indicate that clean air and clear views are important to park visitors. The opportunity to experience unimpaired vistas is just as relevant to a visitor in January as it is in July. Fluctuations in visitation levels are not germane to the goals of the Regional Haze Rule or to the management requirements of the National Park Service and we recommend that this discussion be deleted from the ND draft SIP.

2.2 Cost effectiveness thresholds

In 2011, the North Dakota Department of Environmental Quality (NDDEQ) established cost-effectiveness thresholds for Best Available Retrofit Technology (BART):

- \$4,100/ton for average cost-effectiveness and
- \$7,300/ton for incremental costs effectiveness.

Applying the Chemical Engineering Plant Cost Index to adjust for inflations, these thresholds in 2019\$ are:

- \$4,200/ton for average cost-effectiveness and
- \$7,500/ton for incremental costs effectiveness.

However, EPA has expressed caution regarding using BART costs for Reasonable Progress²:

Given the differences between the BART factors and RP factors and the nature of the applicability criteria that would trigger BART and RP analyses, we do not necessarily consider the cost-effectiveness and visibility benefit values from BART determinations to be directly comparable to RP analyses

It is generally accepted that the cost-effectiveness threshold for Reasonable Progress will be higher as smaller emission units are considered. Other states have set cost-effectiveness thresholds of: \$5,000/ton for EGUs in AR and TX, \$7,000/ton in NM, and \$10,000/ton in CO and OR.

2.3 Visibility benefit & URP

The long-term strategy selected by the state does not include additional controls for any of the sources selected for four-factor analysis, despite the fact there are technically feasible, cost-effective control options for several of the emissions units considered. According to the SIP, the state believes that further controls are not needed because (1) the projected 2028 visibility is below the uniform rate of progress (URP) at the North Dakota Class I areas and (2) potential improvements to visibility from additional reductions would be insignificant. These conclusions are inconsistent with our understanding of the Regional Haze Rule requirements.

Under the CAA (§7491 (g)(1)), reasonable progress determinations *shall* consider the:

“...costs of compliance, the time necessary for compliance, and the energy and nonair quality environmental impacts of compliance, and the remaining useful life of any existing source subject to such requirements;”

² ENVIRONMENTAL PROTECTION AGENCY, 40 CFR Part 52, [EPA-R09-OAR-2013-0588; FRL-9912-97-OAR], Promulgation of Air Quality Implementation Plans; Arizona; Regional Haze and Interstate Visibility Transport Federal Implementation Plan, ACTION: Final rule. September 3, 2014

Reasonable Progress requirements of the rule (40 CFR § 51.308 (f)), states are required to include a long-term strategy that “must include the enforceable emissions limitations, compliance schedules, and other measures that are necessary to make reasonable progress.”

Specifically omitted from this list is the consideration of the visibility benefit of control measures. The rule requires that the state determine the URP needed to meet the goal of unimpaired visibility by 2064. However, EPA has clarified that the URP is not a “safe harbor.” States should not dismiss otherwise technically feasible, cost-effective controls solely because visibility progress in state’s Class I areas is better than the URP. The URP is a planning tool that allows states to evaluate their overall progress toward the goal, but it is not a standard that indicates by itself whether or not progress is reasonable. It may be that a state’s Class I areas are not meeting the URP but the state is still making reasonable progress if it finds by applying four-factor analysis to its sources that there are no technically feasible, cost effective controls to implement. Conversely, it may be that a state’s Class I areas are meeting the URP but are still not making reasonable progress if the state rejects technically feasible cost-effective controls because the Class I areas are below the glideslope. As EPA noted in its July 2021 clarification memo:

The 2017 RHR preamble and the August 2019 Guidance clearly state that it is not appropriate to use the URP in this way, i.e., as a “safe harbor.” The URP is a planning metric used to gauge the amount of progress made thus far and the amount left to make. It is not based on consideration of the four statutory factors and, therefore, cannot answer the question of whether the amount of progress made in any particular implementation period is “reasonable progress.” This concept was explained in the RHR preamble. Therefore, states must select a reasonable number sources and evaluate and determine emission reduction measures that are necessary to make reasonable progress by considering the four statutory factors.

This memo is consistent with earlier guidance from EPA. As EPA noted in the preamble to the 2017 Regional Haze Rule (82 FR 3099):

*The CAA requires that each SIP revision contain long-term strategies for making reasonable progress, and that in determining reasonable progress states must consider the four statutory factors. Treating the URP as a safe harbor would be inconsistent with the statutory requirement that states assess the potential to make further reasonable progress towards natural visibility goal in every implementation period. **Even if a state is currently on or below the URP, there may be sources contributing to visibility impairment for which it would be reasonable to apply additional control measures in light of the four factors.** Although it may conversely be the case that no such sources or control measures exist in a particular state with respect to a particular Class I area and implementation period, this should be determined based on a four-factor analysis for a reasonable set of in-state sources that are contributing the most to the visibility impairment that is still occurring at the*

Class I area. It would bypass the four statutory factors and undermine the fundamental structure and purpose of the reasonable progress analysis to treat the URP as a safe harbor, or as a rigid requirement (emphasis added).

We also note that while trends in visibility conditions show improvement on the most impaired days since 2000, data since 2016 show an increase in haze at Theodore Roosevelt, Badlands, and Wind Cave National Parks (Figure 1). This highlights the need for continuing progress in reducing haze-causing emissions during this planning period.

Figure 1. Visibility on most impaired days for Badlands, Theodore Roosevelt, and Wind Cave National Parks (2000-2020)

In its 2021 memo, EPA also addressed the use of visibility benefit when considering potential emissions controls. Similar to its conclusion regarding the use of the URP, EPA stated that it is not appropriate to reject cost-effective control measures simply because the impact on visibility is considered to be insignificant:

We have observed that some draft SIPs are using modeled visibility benefits to justify rejecting otherwise cost-effective control measures. It is important that, where applicable, each state considers the magnitude of modeled visibility impacts or benefits in the context of its own contribution to visibility impairment. That is, whether a particular visibility impact or change is “meaningful” should be assessed in the context of the individual state’s

contribution to visibility impairment, rather than total impairment at a Class I area. As stated in the RHR preamble:

Regional haze is visibility impairment that is caused by the emission of air pollutants from numerous sources located over a wide geographic area. At any given Class I area, hundreds or even thousands of individual sources may contribute to regional haze. Thus, it would not be appropriate for a state to reject a control measure (or measures) because its effect on the RPG is subjectively assessed as not “meaningful.”

EPA’s 2019 guidance acknowledges that the Clean Air Act does not prohibit a state from considering visibility benefit when determining which control measures are needed to make reasonable progress. However, the RH guidance and the 2021 Clarification Memorandum identify appropriate and inappropriate methods for examining visibility impacts and benefit from individual sources. For example, section II.B.4.g of the guidance notes:

In particular, a state should not use the difference in projected 2028 visibility with and without the control measure (e.g., the effect on the 2028 RPG) as its only characterization of the visibility benefit of the measure.

The guidance explains in a footnote that when using visibility benefits to inform decisions on emissions controls for individual sources, a state should not rely on an estimate of visibility benefits relative to a “dirty background”—that is, a condition where background visibility impairment is greater than natural conditions—because doing so would obscure the full benefits of control measures. However, this is what North Dakota has done. The state compared projected overall visibility conditions at Theodore Roosevelt NP on the most impaired days in 2028 under two scenarios—one with only on-the-books reductions (2028 OTB) and one with potential additional control measures included (2028PAC1)—and concluded that the modeled 0.08 DV difference would not meaningfully improve visibility (pp. 127-128). By choosing 2028 as the projected year for this comparison, the state has made a comparison of visibility conditions quantified in deciviews against a background where visibility conditions are greater than natural conditions (i.e., a “dirty” background).

In addition, the 2028PAC1 modeling run only included additional potential controls from two North Dakota sources. Our analysis shows that there are a number of additional technically feasible, cost-effective controls available for other North Dakota’s sources. The result is that the comparison in projected visibility conditions understates the potential visibility improvements that would result at the park from additional controls.

We request that North Dakota require all control measures found to be technically feasible and cost-effective through analysis of the four factors specified in the Regional Haze Rule.

2.4 Reasonable Progress Costs of Compliance

The “costs of compliance” is the first of the four reasonable progress statutory factors contained in Section 169 of the Clean Air Act.

OVERESTIMATION OF COSTS

In reviewing four-factor analyses presented in the ND draft Reasonable Progress SIP, we identified several re-occurring errors in the cost analyses that generally result in overestimation of costs. As much as possible, we relied upon the most recent versions of EPA's Control Cost Manual (CCM) to identify these errors and inform our calculations. NPS cost analyses for individual ND facilities are described below and documented in the attached calculation spreadsheets.

- Several four-factor analyses applied a 20% Contingency Cost of Direct and indirect capital costs to all capital cost analyses. The CCM says:

The contingency, C, accounts for unexpected costs associated with the fabrication and installation of the absorber and is calculated by multiplying the total direct and indirect costs by a contingency factor (CF). A default value of 10% is typically used for CF.

- Several four-factor analyses applied 2% of Direct cost as Owners' Costs—this is not allowed by EPA.
- In some cases, four-factor analyses include Property Taxes = 1% of TCI. Insurance = 1% of TCI. Administration = 2% of TCI. The CCM says:

property taxes and overhead are both assumed to be zero, and insurance costs are assumed to be negligible. Thus, administrative charges and capital recovery are the only components of indirect annual costs estimated in this analysis.

- Capital costs and lost revenues were annualized using a capital recovery factor based on an annual interest rate of 5.25% and equipment life of 20 years.
 - EPA's Control Cost Manual (CCM) recommends a scrubber and SCR equipment life of 30 years and use of the current prime interest rate (3.25%) unless a site-specific interest rate is justified. The CCM recommends 20 years for SNCR equipment life.

2.5 Selective Catalytic Reduction (SCR) on North Dakota Lignite

SCR is a process by which ammonia (NH₃) reacts with nitric oxide (NO) and nitrogen dioxide (NO₂), collectively NO_x, in the presence of a catalyst to reduce the NO_x to nitrogen (N₂) and water (H₂O). SCR technology has been applied to NO_x-bearing flue gases generated from power generating facilities burning various types of coal, including bituminous, subbituminous, and Texas lignite. The principal reactions resulting in NO_x reduction are:

Because these reactions proceed slowly at typical boiler exit gas temperatures of a coal-fired steam -electric generating unit, a catalyst is used to increase the reaction rate between NO_x and

NH₃. Depending on the specific constituents in the flue gas, a typical temperature range of 550°F to 780°F is necessary to achieve normal performance of the catalyst. For the typical coal-fired boiler, optimal performance will be in the range of approximately 650°F to 750°F.

SCR catalyst deactivation occurs through two primary mechanisms: physical deactivation and chemical poisoning. Physical deactivation is caused by either exposure of the catalyst to excessive temperatures (thermal deactivation) or masking of the catalyst due to entrainment of particulate from the flue gas stream (fouling). Chemical deactivation is caused by either an irreversible reaction of the catalyst with a contaminant in the gas stream (poisoning) or a reversible absorption of a contaminant on the surface of the catalyst (inhibition).

2.5.1 SCR Configurations

In general, there are three candidate SCR configurations that can be employed on coal-fired steam electric generating units. The SCR configuration designations generally describe the location of the SCR reaction vessel in relation to other post-combustion air quality control systems. Candidate SCR configurations include:

- High-dust configuration
- Low-dust configuration
- Tail-end configuration

High-Dust Configuration

In a high-dust configuration, the SCR reactor is located in the flue gas stream between the economizer outlet and the air heater inlet. This configuration locates the SCR within the inherently optimal temperature range environment for NO_x reduction (i.e., 650°F to 750°F); however, flue gas characteristics at the economizer outlet can also have detrimental effects on the SCR catalyst. As an example, the high-dust SCR configuration exposes the SCR catalyst to high levels of fly ash loading. High levels of fly ash can result in significant erosion of the catalyst, resulting in more frequent cleaning cycles and catalyst replacement. A second major concern with the high-dust configuration is the presence of high levels of sodium (both in the vapor-phase and as submicron aerosols) in the North Dakota lignite-derived flue gas. Sodium is a known SCR catalyst poison, and also affects the adhesive and cohesive characteristics of the fly ash, which in turn, would have an adverse effect on the SCR catalyst and reactor vessel.

Low-Dust Configuration

In the low-dust configuration, the SCR reactor vessel is located in the flue gas stream after the particulate collection device (i.e. ESP or FF). The potential advantage of a Low-Dust SCR configuration is that the mechanisms that result in particulate capture may also capture some of the vapor-phase alkali and the alkali-enriched submicron particles, reducing the risk of catalyst poisoning and/or deactivation.

Tail-End Configuration

In the tail-end configuration, the SCR reaction vessel is located in the flue gas stream after the particulate and FGD control systems. The potential advantage of a Tail-End SCR (TE-SCR) configuration is that the mechanisms that capture of SO₂ and particulate will also capture some

of the vapor-phase alkali and the alkali-enriched submicron particles, reducing the risk of catalyst poisoning and/or deactivation.

2.5.2 SCR Technical Feasibility

In evaluating the “Cost of Compliance” (Clean Air Act Statutory Factor #1), potential control strategies must be evaluated for their technical feasibility. There are two components to the technical feasibility determination: **availability** and **applicability**.

SCR is available—it has been applied to numerous coal-fired boilers, including lignite-fired boilers³. The question is whether it is applicable. According to the BART Guidelines:

What do we mean by “applicable” technology?

You need to exercise technical judgment in determining whether a control alternative is applicable to the source type under consideration. In general, a commercially available control option will be presumed applicable if it has been used on the same or a similar source type. Absent a showing of this type, you evaluate technical feasibility by examining the physical and chemical characteristics of the pollutant-bearing gas stream, and comparing them to the gas stream characteristics of the source types to which the technology had been applied previously. Deployment of the control technology on a new or existing source with similar gas stream characteristics is generally a sufficient basis for concluding the technology is technically feasible barring a demonstration to the contrary as described below.

What type of demonstration is required if I conclude that an option is not technically feasible?

Where you conclude that a control option identified in Step 1 is technically infeasible, you should demonstrate that the option is either commercially unavailable, or that specific circumstances preclude its application to a particular emission unit. Generally, such a demonstration involves an evaluation of the characteristics of the pollutant-bearing gas stream and the capabilities of the technology. Alternatively, a demonstration of technical infeasibility may involve a showing that there are unresolvable technical difficulties with applying the control to the source (e.g., size of the unit, location of the proposed site, operating problems related to specific circumstances of the source, space constraints, reliability, and adverse side effects on the rest of the facility).

The primary argument against the applicability of SCR to boilers fired with ND lignite is that the catalyst will experience rapid deactivation.

³ Sandow unit #4 and Oak Grove in Texas

2.5.3 SCR Catalyst Deactivation

SCR catalyst deactivation occurs through two primary mechanisms: physical deactivation and chemical poisoning. Physical deactivation is caused by either exposure of the catalyst to excessive temperatures (thermal deactivation) or masking of the catalyst due to entrainment of particulate from the flue gas stream (fouling). Chemical deactivation is caused by either an irreversible reaction of the catalyst with a contaminant in the gas stream (poisoning) or a reversible absorption of a contaminant on the surface of the catalyst (inhibition).

SCR catalyst poisoning can result from the presence of trace elements and strong alkaline substances in flue gas, including sodium (Na), potassium (K), and calcium (Ca). Alkaline metals can chemically attach to active catalyst pore sites and cause deactivation. Sodium and potassium are of prime concern especially in their water-soluble forms, which are more mobile and can penetrate into the catalyst pores. Earth metals, especially calcium, can react with SO₃ absorbed within the catalyst to form CaSO₄ and blind the catalyst.

ND lignite contains relatively high levels of organically associated alkali and alkaline-earth elements, including Na, Ca, K, and magnesium. Na levels in North Dakota lignite are typically 5 to 20 times higher than Na levels in bituminous and subbituminous coals, and Na compounds can represent between 5% and 11% of the ash generated from firing ND lignite.

EPA guidance recommends a demonstration of technical infeasibility “*involves an evaluation of the characteristics of the pollutant-bearing gas stream.*” In the first planning period, NDDEQ relied upon testing of SCR catalyst described as follows:

To evaluate deactivation rates on a North Dakota lignite-fired boiler, [U of ND Energy & Environmental Research Center] EERC and several utilities and catalyst vendors conducted pilot scale testing at the Coyote Station in 2003-2004. The pilot scale test reactor SCR deployed at the Coyote Station became plugged and the catalyst pores deactivated after 2 months of operation (approximately 1,430 hours). This deactivation rate is significantly faster than the deactivation rate observed on bituminous and subbituminous coal-fired units, which can achieve catalyst life ranging between 10,000 and 30,000 operating hours. The EERC described the deactivation at the Coyote Station as extremely rapid and severe. NDDEQ prepared a comprehensive technical feasibility assessment of high dust SCR on lignite-fired boilers during the first planning period. The Department concluded, based on the unique characteristics of North Dakota lignite-derived flue gas, that the high-dust SCR configuration was not a technically feasible or commercially available NO_x control option for North Dakota lignite-fired boilers.

This “demonstration” was conducted on a pilot-scale SCR located in a high-dust configuration on a cyclone boiler firing ND lignite; this narrow, 17-year-old, demonstration does not apply to SCR in either a low-dust or tail-end configuration or on other types of boilers. The burden to demonstrate that the gas stream characteristics would render SCR technically unfeasible rests upon the source owner. Because these are existing emission units, the source owners have had

many years to test emissions downstream of the emission control systems. We are not aware that any such testing has been conducted or results made available. In the absence of such demonstrations, we conclude that tail-end SCR is technically-feasible on boilers firing ND lignite. Ultimately, the rate of catalyst deactivation is a factor to be considered in the economic analysis, not in the technical feasibility determination.

During the first regional haze program planning period in North Dakota, the ND Department of Environmental Quality (NDDEQ) determined that installation of SCR in any configuration was not a technically feasible control technology because it had not been demonstrated in practice on ND lignite. However, the earlier determination was based upon pilot testing on cyclone-fired boilers in a high-dust configuration. Also, some source owners (through their consultants) argued that SCR is not technically feasible because catalyst vendors concluded that they would not be able to provide a catalyst life guarantee for either low-dust or tail-end SCR without pilot-scale testing. However, the absence of a vendor guarantee does not mean that a technology is infeasible.

Now, NDDEQ is saying that:

Successful use of Tail-End SCR (TE-SCR) controls have since been demonstrated at existing bituminous- and subbituminous-fired units. Therefore, the current determination is deeming TE-SCR as being technically feasible on tangentially-fired and wall-fired boilers burning North Dakota lignite.⁴

We note that NDDEQ continues to say that SCR is not technically-feasible in any configuration of cyclone boilers burning ND lignite.⁵

2.5.4 SCR Effectiveness

NDDEQ assumed that TE-SCR could achieve 0.05 lb/mmBtu. However, Tail-End SCR should be able to reduce NO_x emissions by up to 90% and achieve 0.04 lb/mmBtu. For example, CAMD data contains 11 coal-fired EGUs with SCR at 0.04 lb/mmBtu annual average.

⁴ Tangentially-fired Units 1 and Unit 2 at Antelope Valley Station and Coal Creek Station, as well as the wall-fired Unit 1 at Leland Olds Station.

⁵ Coyote Station, Leland Olds Station Unit 2, Milton R. Young Station Units 1 and 2.

Table 1. Coal-Fired EGUs with SCR at 0.04lb/mmBtu Annual Average

State	Facility Name	Unit ID	Avg. NO _x Rate (lb/MMBtu)	Unit Type
WI	Edgewater (4050)	5	0.04	Dry bottom wall-fired boiler
KY	Trimble County	2	0.04	Dry bottom wall-fired boiler
TX	J K Spruce	**2	0.04	Tangentially-fired
WY	Dry Fork Station	1	0.04	Dry bottom wall-fired boiler
KS	Jeffrey Energy Center	1	0.04	Tangentially-fired
KY	E W Brown	3	0.04	Tangentially-fired
IA	Walter Scott Jr. Energy Center	4	0.04	Dry bottom wall-fired boiler
IA	Lansing	4	0.04	Dry bottom turbo-fired boiler
AR	John W. Turk Jr. Power Plant	SN-01	0.04	Dry bottom wall-fired boiler
TX	W A Parish	WAP7	0.04	Tangentially-fired
TX	Sandy Creek Energy Station	S01	0.04	Dry bottom wall-fired boiler

Furthermore, EPA assumed in 2014 that SCR could achieve the 0.04 lb/mmBtu annual emission rate proposed by Basin Electric at its Laramie River Station in WY.

2.5.5 SCR Cost Elements

Successful operation of the tail-end configuration might also require a heat exchanger to reheat the flue gas. However, special catalysts are available that operate at lower or higher temperatures. According to SCR vendor Ceram:

Our honeycomb catalyst can be tailored to customer specifications by varying the vanadia content. Our products are suitable for temperatures between 150°C and 550°C /300°F and 1020°F.

According to EPA's Control Cost Manual (CCM):

A tail-end system may have higher capital and operating costs than the other SCR systems because of the additional equipment and operational costs associated with flue gas reheating and heat recovery. However, these costs are in part offset by reductions in catalyst costs. Tail-end units require less catalyst because they can use catalysts with smaller pitch and higher surface area per unit volume. Tail-end SCR typically require only 2 layers of catalyst, although some use four half-layers of catalyst to allow for greater flexibility for catalyst replacement. In addition, because there is less fly ash, catalyst poisons, and SO₂ in the flue gas for tail-end units, the catalyst lifetime is

significantly increased, and less expensive catalyst may be used. Some sources have reported catalyst lifetimes for tail-end SCRs to be over 100,000 hours. The tail-end SCRs may also have longer lifetimes due to the lower operating temperatures and lower levels of dust and SO₃.

Please see EPA Control Cost Manual Chapter 2, Selective Catalytic Reduction, June 2019; (§2.2.3 SCR System Configurations pg's 34-35) for more information on TE-SCR.

2.5.6 Conclusions & Recommendations

- NDDEQ has determined that Tail-End Selective Catalytic Reduction (TE-SCR) is technically-feasible on tangentially-fired and wall-fired boilers burning ND lignite.
- Catalyst deactivation is normal; the rate of deactivation is an economic factor rather than a technical-feasibility issue.
- No demonstration has been provided that TE-SCR is not feasible on cyclone boilers burning ND lignite. We conclude that TE-SCR is technically-feasible on these boilers.
- SCR can achieve NO_x rates as low as 0.04 lb/mmBtu.
- Capital and operating costs of TE-SCR likely warrant further evaluation.

3 Specific Review of Four-Factor Analyses

3.1 Coyote Station

3.1.1 Summary of NPS Recommendations and Requests for Coyote Station

NPS review of the four-factor analysis conducted for Coyote Station (Coyote) finds that there are technically feasible and cost-effective opportunities available to further control SO₂ and NO_x emissions from Unit 1. In fact, we find that the cost of control is more economical than estimated when analyses are adjusted in accordance with the EPA Cost Control Manual.

Although ND has not established a cost threshold for this round of regional haze planning, we can advise that other states have set cost-effectiveness thresholds of: \$5,000/ton for EGUs in AR and TX, \$7,000/ton in NM, and \$10,000/ton in CO and OR.

The cost effectiveness of replacing the existing SO₂ scrubber at Coyote would be acceptable in the context of the previous ND BART thresholds as well as the thresholds used by the states listed above. Replacement of the existing dry scrubbers with modern new scrubbers could cost-effectively reduce facility SO₂ emissions by almost 11,600 tons/yr.

We find at least two cost effective opportunities for reducing NO_x emissions at Coyote. 1) The addition of SNCR + RRI very cost effective and could reduce NO_x emissions by almost 4,000 tons/yr. 2) The average cost effectiveness of adding SCR at Coyote would also be acceptable in the context of the previous ND BART thresholds as well as the thresholds used by the states cited. Addition of SCR could reduce facility NO_x emissions by almost 5,700 tons/yr.

We recommend that ND take every opportunity to reduce SO₂ and NO_x emissions from the Coyote Station in this planning period. By requiring implementation of identified controls ND will be reducing haze causing emissions and advancing incremental improvement of visibility at Theodore Roosevelt, Badlands, and Wind Cave National Parks as well as other Class I areas in the region.

3.1.2 Plant Characteristics

Coyote Station (Coyote) is a lignite coal-fired power station operated by Otter Tail Power near Beulah, North Dakota, 109 km east of Theodore Roosevelt National Park, a Class I area administered by the National Park Service (NPS).

Of 3,317 Electricity Generating Units (EGUs) in EPA's Clean Air Markets Database (CAMD) in 2020, Coyote ranked #5 for sulfur dioxide (SO₂) emissions (11,975 ton) and #4 for nitrogen oxides (NO_x at 5,883 tons). Coyote's carbon dioxide emissions of 2,909,521 tons rank #112 in the US. Coyote also ranked #42 for EGU mercury (Hg) emissions with 81 lb in 2017.

The facility is a single unit station with one 450 MW Babcock and Wilcox subcritical cyclone boiler (Coyote Unit 1). Coyote Unit 1 is designed to fire North Dakota lignite and is equipped with separated overfire air (SOFA) for NO_x control, and dry flue gas desulfurization (DFGD or dry FGD) and a fabric filter baghouse (FF) for SO₂ and particulate matter (PM) control. Coyote began Halogenated Powdered Activated Carbon Sorbent Injection Apr 16, 2015 to comply with

the Mercury and Air Toxics Standards. Lignite is delivered to the Station from the Coyote Creek Mine, whose primary operations are approximately 3-4 miles from the Coyote Station.

3.1.3 First Planning Period Reasonable Progress Control Requirements for Coyote Station

Coyote Unit 1 commenced operation in 1981 and was not classified as a BART -eligible source or subject to the BART requirements. Nevertheless, during the initial planning period, the North Dakota Department of Environmental Quality (NDDEQ) evaluated emissions from the Coyote Station as a Reasonable Progress (RP) source. The RP analysis prepared by NDDEQ concluded that no additional controls would be required on Coyote Unit 1 during the initial planning period; however, NDDEQ and Otter Tail reached an agreement whereby Otter Tail committed to install SOFA equipment to reduce NO_x emissions. SOFA began Jun 15, 2016 and the effects can be seen on the chart below.

Figure 2. Calculated Avg. NO_x Rate for Coyote Station Unit 1 (1995-2020)

Coyote Unit 1 is equipped with 12 ten-foot cyclones, six on the front wall and six on the rear wall, two levels of three on each wall. The lignite coal requires a pre-dry system, which conveys the coal through individual crushers and into a cyclone separator for moisture separation. The dried coal is discharged from the bottom of the separator through a rotary seal, while the transport air (with a small quantity of fines) is discharged out the top and into ports above the cyclones. The coal discharged through the bottom rotary seal is blown into the cyclone through a pipe referred to as the "lift line" or known as primary air on most other similar installations. The temperature of the pre-dry air/coal temperature is regulated along with the lift line air by injecting cold (tempering) air into the hot primary air stream to regulate the outlet temperatures.

In 2016, The Babcock and Wilcox Company (B&W) installed fourteen separated overfire air (SOFA) ports (seven on the front and rear wall) and modified the cyclones with smaller re-entrant throats and a Vi - Vi split air damper (each having its own damper) to reduce NO_x

emissions. For the SOFA process, the injection of air into the boiler is staged into two zones, in which approximately 5% to 20% of the total combustion air is diverted from the burners and injected through ports located above the top burner level. Staging of the combustion air reduces NO_x formation by two mechanisms. First, staged combustion results in a cooler flame which will reduce the formation of thermal NO_x. Second the staged combustion results in less oxygen reacting with fuel molecules. The degree of staging is limited by operational problems since the staged combustion results in incomplete combustion conditions and a longer flame profile. The units normally operate with the damper closed or nearly closed to help recirculate the coal in the cyclone and allows for increased coal retention and improved combustion. Since the SOFA installation, Coyote Unit 1 has achieved average controlled NO_x emissions approximately 0.46 lb/MMBtu.

S&L for Coyote: Tuning of the cyclone boiler to optimize the combustion process and minimize the generation of NO_x was recently completed at Coyote Unit I. Tuning was completed by lowering the stoichiometry (i.e., lower the air-to-fuel ratio) in the cyclone barrel and tracking the cyclone combustion stability, while staying within the OEM specifications for best combustion engineering practice. Based on the testing results, Coyote Unit 1 was able to achieve average NO_x emissions of approximately 0.42 lb/MMBtu without obvious impacts to boiler performance and with minimal slagging. Based on the results of the combustion turning tests, combustion optimization is considered a technically feasible NO_x control option.

NPS: The 2016–2020 NO_x average was 0.448 lb/mmBtu. (EPA Guidance⁶ recommends use of five years of recent emissions data.⁷) The tuning and combustion optimization efforts appear to have yielded a 34% reduction compared to NO_x emissions prior to the 2016 efforts. (We are not aware of any similar efforts to reduce SO₂ emissions at Coyote.)

⁶ final_signed_7-8-21_regional_haze_clarifications_memo

⁷ Information on a source's past performance using its existing measures may help to inform the expected future operation of that source. If either a source's implementation of its existing measures or the emission rate achieved using those measures has not been consistent in the past, it is not reasonable to assume that the source's emission rate will remain consistent and will not increase in the future. To this end, states should include data for a representative historical period demonstrating that the source has consistently implemented its existing measures and has achieved, using those measures, a reasonably consistent emission rate. For most sources, data from the most recent 5 years (if available) is sufficient to make this showing. Information pertinent to a source's implementation of its existing measures going forward is also critical to a state's demonstration. States should provide data and information on the source's projected emission rate (e.g., for 2028), including assumptions and inputs to those projections. States should justify those assumptions and inputs and explain why it is reasonable to expect that the source's emission rate will not increase in the future.

Figure 3. Calculated Avg. SO₂ Rate for Coyote Station Unit 1 (1996-2020)

In the initial planning period SIP, NDDEQ noted that additional SO₂ and NO_x controls for Coyote Unit 1 would be reevaluated during future planning periods to determine if additional emissions reductions would be required.

3.1.4 Second Planning Period Reasonable Progress Control Requirements for Coyote Station

NDDEQ: Otter Tail Power Company submitted their original four-factors analysis to the NDDEQ on January 30, 2019. A revised four factors analysis was submitted on May 10, 2019 in response to comments from the NDDEQ, which were submitted to Otter Tail Power Company on March 20, 2019. Another revised four factors analysis was submitted to the NDDEQ on January 6, 2020 to update the costs for the installation and operation of selected non-catalytic reduction (SNCR) and rich reagent injection (RRI). A final update to the four factors analysis was submitted to the NDDEQ on June 8, 2020 to update the analysis associated with some of the SO₂ controls evaluated.

SO₂ Analysis

SO₂ technology excerpts from the Sargent & Lundy (S&L) reports prepared for Coyote Station.

EXISTING FGD + DRY SORBENT INJECTION

Sorbent injection (dry or wet) upstream of the existing dry scrubber is a technically feasible and commercially available SO₂ control option for Coyote Unit 1. Taking into consideration the fact that Coyote is currently equipped with a calcium-based dry scrubbing system, hydrated lime dry sorbent injection would be the most practical, and potentially the most effective, sorbent injection control option. Sodium-based systems would require extensive testing to determine the potential impacts associated with introducing significant quantities of sodium into the existing system, and are not considered practical control options for Coyote Unit 1.

Based on engineering judgment, and assuming adequate residence time in the duct work upstream of the existing dry scrubber, hydrated lime injection could reduce SO₂ concentrations at the dry scrubber inlet by approximately 35%. Based on future design fuel characteristics, this would reduce SO₂ concentrations at the dry scrubber inlet from approximately 3.12 lb/MMBtu to approximately 2.03 lb/MMBtu. Applying the current scrubber SO₂ removal efficiency of 71% (dry scrubber plus fabric filter), would result in a controlled SO₂ emission rate of 0.58 lb/MMBtu. DSI upstream of the existing dry scrubbing system is considered a technically feasible SO₂ control technology; however, flow modeling and field testing at Coyote Unit 1 would be needed to ensure that adequate residence time is available for SO₂ control and to confirm the incremental reduction in SO₂ emissions achievable without creating unacceptable operational issues.

EXISTING DFGD OPERATIONAL IMPROVEMENTS AND EQUIPMENT UPGRADES

Operational and other design changes/upgrades to the existing dry scrubber may provide an opportunity for additional SO₂ removal and allow the unit to achieve lower controlled SO₂ emissions. S&L working with OTP personnel, identified a number of potentially feasible operational changes that may be available to increase SO₂ removal efficiency with the existing equipment. A discussion of each of these options is provided in the following sections.

Lime Quality

Based on a review of available lime analyses, and a review of operating data from the existing lime slaking system. Coyote Unit 1 currently procures a high-quality lime for use in the dry scrubbers. The typical CaO content of the lime used at Coyote is 90% or greater, and, when slaked, can achieve a 39.4 °C temperature rise in 3 minutes of adding water. For these reasons, changing the lime quality is not considered a technically-feasible operational change available to control SO₂ emissions from Coyote Unit 1 and will not be evaluated further.

Ca:S Stoichiometric Ratio

Based on information provided by the station, the DFGD system on Coyote Unit 1 currently operates the recycle system at approximately 24% solids. The Coyote Unit 1 recycle system is operating within the original design conditions and system capacity. The plant has tested higher recycle rates (up to 28-30% solids), but at these higher rates plant personnel reported significant problems with the atomizer wheels spilling over and pluggage of various strainers. Based on the adverse operational impacts observed during these tests, as well as the design limitations of the existing dry scrubber modules, increasing the recycle % solids is not considered a technically feasible SO₂ control option for Coyote Unit 1.

As an alternative to increasing the recycle rate, the Ca:S stoichiometric ratio in the system may be increased by increasing the quantity of fresh lime introduced to the system. Testing was completed in October 2018 on Coyote Unit 1 to determine the impact of increasing the amount of fresh lime slurry fed to the atomizer feed tanks while adjusting the amount of recycle slurry in order to maintain the design 24% solids to the absorber. During the test program, Coyote Unit 1 was able to achieve an average controlled SO₂ emission rate of 0.50 lb/MMBtu without

significant adverse operational impacts and represents an average emission rate that Coyote would be expected to achieve on an on-going long-term basis under normal operating conditions.

Increasing the quantity of fresh lime introduced to the system will require the existing atomizer wheels to be upgraded from the eight-nozzle wheel to a twelve-nozzle wheel to mitigate for potential plugging and spill over issues caused by the percent solids limitation of the existing atomizer wheels, and to prevent the possibility of moisture carry-over that could occur with the increase in lime slurry flow. Although upgrades to the existing atomizer wheels and nozzles will be required, increasing the Ca:S stoichiometric ratio by adding additional fresh lime to the system is considered a technically feasible SO₂ control option for Coyote Unit 1, and will be included in the Four-Factor Analysis.

Approach to Saturation Temperature

The Coyote Unit 1 dry scrubbers currently operate at an outlet temperature of 190-210 °F, which is approximately 55-75 °F above the adiabatic saturation temperature and within original the OEM design steady-state operating parameter of 190 °F at the stack. More recent dry scrubbing systems have been designed to operate at 30 °F approach to adiabatic saturation. The station has attempted to lower the outlet temperatures to 165-170°F; however, this change caused significant corrosion of the absorber vessels and downstream equipment. Corrosion was likely due to the fact that the Coyote Unit 1 scrubbers were not able to completely dry the slurry droplets because the absorber vessels were designed with a residence time of approximately 1.0 second. More-recent dry scrubbers are designed with approximately 10 seconds of residence time. The low residence time at Coyote limits the scrubbers' ability to dry all slurry droplets when the system is operated too close to the approach to adiabatic saturation temperature. Due to the design limitations of the existing absorber vessels, reducing the outlet temperature is not considered a technically feasible SO₂ control option for Coyote Unit 1, and will not be evaluated further.

Atomizer Replacement

Based on S&L's assessment of the existing control system, previous testing completed by the station, and input from station operators, the existing DFGD system is limited in residence time, and the ability to increase the recycle ratio (solids content) to allow for more effective Ca:S contact in the scrubber vessels. The existing atomizers with eight-nozzle wheels would need to be upgraded to a twelve-nozzle wheel to mitigate for potential plugging and spill-over issues that could occur with the increased Ca:S stoichiometric ratio

Based on engineering judgment, new 12-nozzle atomizers would improve spray atomization to produce slurry droplets that are smaller in size than the droplets produced by the existing nozzle design. Improved materials of construction would also allow for higher solids content in the slurry without detrimental equipment pluggage or spill-over.

Replacing the existing nozzles with a more recent 12-nozzle wheel design would provide better atomization of the slurry spray and allow for more effective Ca:S contact in the absorber vessels. However, nozzle replacement would not, on its own, be expected to provide a significant increase in SO₂ control. Nozzle upgrades coupled with operational changes designed to increase

the Ca:S stoichiometric ratio is a technically feasible option that would be expected to provide additional SO₂ control.

Slaker Replacement

Lime slurry, the reagent used for SO₂ removal in a dry scrubber, is produced by mixing pebble lime with heated water in a slaker; this process is referred to as "slaking". The slaker is operated at an optimum water-to-lime ratio (typically between 3:1 and 6:1) to produce lime slurry by metering the amount of water and the amount of lime added to the slaker. Slakers are typically designed to produce a lime slurry between 15-20% solids.

The lime slurry is added to recycle slurry in a mix tank and then sent to the atomizer where it is sprayed into the scrubber for SO₂ removal. Coyote Unit 1 still operates the original Dorr-Oliver detention slakers. The slakers operate at a 5:1 water-to-lime ratio and approximately 18% solids, which is in line with the design as well as industry practice. Therefore, replacing the slakers would not result in improved Ca:S contact in the absorber vessels or provide additional SO₂ removal. Replacing the lime slakers is not considered a technically feasible SO₂ control option for Coyote Unit 1, and will not be evaluated further.

FGD Operational Improvements + DSI

Technically feasible FGD operational improvements include increasing the Ca:S stoichiometric ratio of the FGD by introducing additional fresh lime to the absorber modules. Based on engineering judgement, layering FGD operational improvements with DSI could reduce SO₂ emissions from the baseline SO₂ emission rate of 0.85 lb/MMBtu to approximately 0.33 lb/MMBtu at Coyote Unit 1. However, as stated previously, flow modeling and field testing at Coyote Unit 1 would be needed to ensure that adequate residence time is available for SO₂ control and to confirm the incremental reduction in SO₂ emissions achievable without creating unacceptable operational issues.

Adding an Absorber Module

Another option for extending the residence time within the reactor modules and increasing Ca:S contact would be to add an additional absorber module. The existing system is designed with four absorber modules that share three fabric filter zones. The system is designed to operate with four modules at full load, three or four modules at 75% load and two modules at 50% load. At full load, the flue gas residence time in the reactor modules is approximately 1.0 second. More recent dry scrubbing systems have been designed with reaction vessel residence times of 10 seconds or more.

One potential option available to the Coyote Station to increase absorber module residence time would be to add an additional absorber module to the existing dry scrubbing system. The number of absorber modules used in a DFGD system is dependent on multiple operating parameters, including the flue gas flow rate and SO₂ concentrations. DFGD absorber modules are typically specified with minimum and maximum flue gas flow rates. If the absorber modules are oversized, flue gas velocities through the module can be too low, causing solids dropout inside the vessel. If the absorber modules are undersized, flue gas velocities can be too high, causing residence time to fall below recommended levels.

Dry scrubbing units that are operating at flue gas volumes significantly above the design flow rate can benefit from adding an extra module to the system. The module would be placed in parallel with the existing modules to achieve a similar pressure drop through each vessel and to ensure equal flue gas distribution to the vessels. Although adding an absorber module would likely allow additional residence time for the SO₂ removal reactions to occur, it would require extensive engineering and modifications to the existing system. More importantly, the Coyote Unit 1 absorber module design is no longer available from Combustion Engineering, and it would likely not be possible to procure a commercial offering from another technology vendor that would be compatible with the existing modules. Therefore, incorporating an additional absorber module into the existing system is not a commercially available or technically feasible SO₂ control strategy for Coyote, and will not be evaluated further.

Replacing Existing Absorbers with New Absorber Modules

Removed from Four-factor Analysis—see discussion below.

FGD Upgrades – Replace Existing Absorbers with Two New Absorbers

(Adjacent to Existing FF + Increased Lime Injection)

One of the technically feasible sulfur dioxide control technologies presented to the NDDEQ in the initial Four-Factor Analysis for Coyote Station Unit 1 involved retrofitting the existing dry flue gas desulfurization (DFGD) system with new absorber modules. This option was specifically limited to dismantling Coyote Station Unit 1's existing absorber modules and installing new reactor absorbers in the same location. The same location was used for the retrofit absorbers as the existing DFGD because, at the time of the initial Four-Factor Analysis, it was predicted that redirecting flue gas to a different location would likely result in significant solids dropout and other operational issues.

Since submittal of the Four-Factor Analysis, OTP became aware of a recent successful project by Babcock and Wilcox (B&W) that involved redirecting flue gas to a new SDA module located adjacent to an existing fabric filter. Therefore, OTP engaged B&W and Sargent & Lundy to perform a supplemental evaluation of this option for Coyote Station Unit 1.

B&W evaluated single module and two-module equipment arrangements for Coyote Station Unit 1. Given B&W's extensive project experience and Coyote Station's operating conditions, B&W's evaluation focused on the two-module design in order to confidently treat 100% of the Coyote Station Unit 1 flue gas. B&W's evaluation determined that Coyote Station's flue gas could in fact be re-directed through two new 62 ft. diameter modules located adjacent to the existing Coyote Station Unit 1 DFGD, and then following the new SDA modules, the flue gas could be routed back to the existing Reverse Air Fabric Filter (RAFF). The expected performance of this arrangement is an average controlled SO₂ emission rate of approximately 0.09 lb/MMBtu at Coyote Station Unit 1. Based on this additional evaluation by Sargent & Lundy and B&W, re-directing Coyote Station's Unit 1 flue gas to two new absorber modules adjacent to the existing fabric filter is considered a technically feasible option.

Install New Dry FGD System

Since the new two-SDA-module option is substantially lower in annualized costs and achieves the same emissions reductions as compared to the prior Four-Factor Analysis option for a new Dry FGD, the new Dry FGD option was removed from the cost effectiveness table.

Install New Wet FGD System

A large majority of the wet FGD systems designed to remove SO₂ from existing high-sulfur utility boilers have been designed as wet limestone scrubbers with spray towers and forced oxidation systems. Therefore, for this evaluation, it was assumed that the WFGD control system would be designed as a limestone spray tower scrubber with forced oxidation. Other potentially available wet scrubber designs are not included in this evaluation because the chemistry involved in all wet scrubbing systems are essentially identical, alternative designs would not provide any additional SO₂ control, and control system costs would be similar.

Wet Limestone Scrubbing

For this evaluation it was assumed that the existing Coyote Unit 1 dry scrubber reactor vessels would remain in place, and that the WFGD control system would be located downstream of the existing FFs and ID fans, most likely northeast of the unit's existing dry scrubber/FF. Dry scrubber reactor vessel internals would ultimately be removed to reduce pressure drop through the system. A single WFGD absorber tower would be sufficient for the Coyote Unit 1 flue gas flow. In addition to the absorber tower and reaction vessel, the WFGD control system would require a limestone handling and preparation system and by-product dewatering systems. Because of the saturated nature of the flue gas exiting the WFGD, a new stack with a liner capable of wet flue gas operation would be required. New booster ID fans would also be required to account for the additional pressure drop through the WFGD control system.

Based on engineering judgment and information from control system vendors, it is anticipated that a retrofit WFGD control system on a North Dakota lignite-fired unit would be designed to achieve an SO₂ removal efficiency of approximately 98%. This removal efficiency represents what the control system vendor would be willing to guarantee upon initial operation of the system. On Coyote Unit 1, 98% removal would result in an average controlled SO₂ emission rate of approximately 0.06 lb/MMBtu and represents an average emission rate that Coyote would be expected to achieve on an on-going long-term basis under normal operating conditions.

NO_x Analysis

NO_x technology excerpts from the Sargent & Lundy (S&L) reports prepared for Coyote Station.

TECHNICAL FEASIBILITY OF AVAILABLE NO_x CONTROL OPTIONS

Potentially available NO_x control options were evaluated for technical feasibility (i.e., availability and applicability to Coyote Unit 1) based on a review of physical, chemical, and engineering principals, and an assessment of commercial availability. Options deemed to be technically infeasible, or options that have no practical application to Coyote Unit I, were eliminated from further review. S&L evaluated the effectiveness of the control options

determined to be technically feasible, and established an emission performance level (i.e., controlled emission rate) for each.

Selective Non-Catalytic Reduction

Selective non-catalytic reduction (SNCR) involves the direct injection of ammonia (NH₃) or urea (CO(NH₂)₂) in an oxidizing environment. The ammonia or urea reacts with NO_x in the flue gas to produce N₂ and water as shown below.

Flue gas temperature at the point of reagent injection can greatly affect NO_x removal efficiencies and the quantity of NH₃ or urea that will pass through the SNCR unreacted (referred to as NH₃ slip). In general, SNCR reactions are effective in the range of 1,600°F - 2,100°F. At temperatures below the desired operating range, the NO_x reduction reactions diminish and unreacted NH₃ emissions increase. Above the desired temperature range, NH₃ is oxidized to NO₂, resulting in low NO₂ reduction efficiencies.

SNCR can be applied on cyclone boilers due to having reasonable temperature windows and residence time; however, the potential NO_x reduction is boiler-specific. SNCR has been used as a retrofit NO_x control system of on pulverized coal, fluidized bed boilers, and cyclone boilers. Furthermore, SNCR can be implemented on boilers equipped with low-NO_x burners, overfire air, or SOFA systems. Based on the boiler residence time, temperature profile, and stoichiometry, as well as input from SNCR OEMs, it is estimated that an SNCR system could achieve an average controlled NO_x emission rate of approximately 0.28 lb/MMBtu (approximately 39% below the baseline emission rate of 0.46 lb/MMBtu) at full load while limiting ammonia slip to 10 ppmvd.

NPS: SNCR was added to a similar-sized (477 MW) cyclone boiler burning ND lignite at the M.R. Young Station in late 2010. As a result, NO_x emissions reduced by 53% (from 0.70 lb/mmBtu to 0.33 lb/mmBtu).

Rich Reagent Injection

Similar to SNCR, the concept of rich reagent injection (RRI) is to use a nitrogen-containing additive (e.g., urea) injected into a reducing environment to promote NO_x removal. RRI is a commercial technology for cyclone boilers only. Due to the changes of the lower furnace stoichiometry, RRI is often not a technically feasible option at low loads. Once the stoichiometric ratio increases to >1.0, the potential exists for NO_x generation due to the reaction of NH₃ with oxygen, especially if the injection location and rate is not optimized. Based on these limitations, RRI is considered most effective at full load.

The RRI process is a commercially available process. Based on engineering judgment, RRI is expected to reduce NO_x emissions by approximately 20-40% at Coyote Unit 1 when operating at full load with minimal ammonia slip. However, due to the cyclone combustion temperature window, this technology only provides effective NO_x reduction at or near full load. At low loads, RRI does not provide effective control; however, RRI can be combined with SNCR to provide NO_x control across the full range of normal operating loads. RRI is a technically feasible NO_x

reduction option for North Dakota lignite-fired cyclone boilers. However, due to its limited operating conditions and ineffective NO_x reduction at low loads, RRI alone is not considered an available NO_x control option, and will only be evaluated in conjunction with SNCR.

NPS: Burns & McDonnell estimated that addition of RRI to the 477 MW cyclone Unit #2 at the M.R. Young Station could reduce NO_x emissions by 22% below the current emissions (0.33 lb/mmBtu) from the SNCR system down to 0.26 lb/mmBtu.

SNCR + RRI

While RRI alone will provide beneficial NO_x reduction at full load only, coupling RRI with SNCR can provide a balanced approach to NO_x reduction through all load ranges. Since RRI and SNCR injectors are located at different elevations of the furnace and in different temperature windows, there are not concerns of spatial impacts. The combined system would utilize a relatively high urea injection rate, staged at multiple locations throughout the boiler. The main advantage of this combined system is that the SNCR can provide better NO_x reduction at low load and at a lower NSR than RRI alone: thus, the combined system is expected to provide effective NO_x control across all normal operating load ranges. Coupling RRI and SNCR is considered a technically feasible and commercially available NO_x control technology option on Coyote Unit 1. Based on input from SNCR OEMs and engineering judgment, the control option is expected to achieve an average outlet NO_x rate of approximately 0.20 lb/MMBtu with an ammonia slip of 10 ppmvd.

NPS: Compared to the estimates for SNCR+RRI at MRYS#2, this may be slightly optimistic.

Gas Reburn

Gas reburn is a retrofit technique that has been used to control NO_x emissions from coal- and oil-fired boilers. Gas reburn involves combustion in three distinct zones within the boiler: (1) a primary combustion zone, where the primary fuel is fired using conventional burners; (2) a reburn zone, where secondary fuel, typically natural gas, is introduced into the boiler; and (3) an OFA burnout zone.

Gas reburn can have a positive impact on NO_x emissions: however, in order to make a meaningful prediction of the NO_x removal capabilities at Coyote Unit 1, extensive testing would be required because gas reburn performance is significantly dependent upon boiler operating characteristics. More importantly, the lack of natural gas available at the Coyote Station precludes the ability to test and implement this control option on Coyote Unit 1. For these reasons, gas reburn is not considered an available or technically feasible NO_x control technology at Coyote Unit 1.

NPS: Although this technology is available, it is probably not economically feasible.

Selective Catalytic Reduction

SCR is a process by which ammonia reacts with nitric oxide (NO) and nitrogen dioxide (NO₂), collectively NO_x, in the presence of a catalyst to reduce the NO_x to nitrogen (N₂) and water. SCR technology has been applied to NO_x-bearing flue gases generated from power generating

facilities burning various types of coal, including bituminous, subbituminous, and Texas lignite. The principal reactions resulting in NO_x reduction are:

Because these reactions proceed slowly at typical boiler exit gas temperatures of a coal-fired steam electric generating unit, a catalyst is used to increase the reaction rate between NO_x and ammonia. Depending on the specific constituents in the flue gas, a typical temperature range of 550°F to 780°F is necessary to achieve normal performance of the catalyst. For the typical coal-fired boiler, optimal performance will be in the range of approximately 650°F to 750°F.

NPS: Special catalysts are available that operate at lower or higher temperatures. Ceram:

Our honeycomb catalyst can be tailored to customer specifications by varying the vanadium content. Our products are suitable for temperatures between 150°C and 550°C / 300°F and 1020°F.

In general, there are three candidate SCR configurations that can be employed on coal-fired steam electric generating units. The SCR configuration designations generally describe the location of the SCR reaction vessel in relation to other post-combustion air quality control systems. Candidate SCR configurations include:

- High-dust configuration
- Low-dust configuration
- Tail-end configuration

Because there are unresolved issues associated with catalyst poisoning, catalyst blinding and plugging, and catalyst erosion, and engineering solutions have not been determined or demonstrated and the high dust configuration has not moved beyond pilot scale testing, high dust SCR is not an available technically feasible NO_x control technology for Coyote Unit 1.

Low-Dust Configuration

In the low-dust configuration, the SCR reactor vessel is located in the flue gas stream after the particulate collection device (i.e., ESP or FF). Because Coyote Unit 1 is equipped with existing dry FGD/FF controls, low-dust SCR has no practical application on the unit, and low-dust SCR is not considered a technically feasible NO_x control option for Coyote Unit 1.

Tail-End Configuration

In the tail-end configuration, the SCR reaction vessel is located in the flue gas stream after the particulate and FGD control systems. The potential advantage of a tail-end SCR configuration at Coyote Unit 1 is that the flue gas will have passed through the dry FGD/FF system prior to the SCR catalyst. As such, there is the possibility that the mass transfer mechanism that results in the capture of SO₂ will also capture some of the vapor-phase sodium and the sodium-enriched submicron particles, reducing the risk of catalyst poisoning and/or deactivation.

NPS: We recommend that Basin should test the gas stream exiting the baghouse to properly evaluate this potential issue.

S&L for Coyote: During the first planning period, NDDEQ initially concluded, based on preliminary information provided by SCR catalyst vendors, that the tail-end SCR configuration would be a technically feasible option for units firing North Dakota lignite that are subject to BART requirements. However, as part of the Milton R. Young Station (MRYS) NO_x BACT determination process, detailed information describing the expected ash characteristics and flue gas characteristics was provided to two SCR catalyst vendors (CERAM Environmental, Inc. (CERAM) and Haldor Topsoe, Inc.). Based on their review of the data, both vendors concluded that they would not be able to provide a catalyst life guarantee for either low-dust or tail-end SCR without pilot-scale testing.

NPS: The applicability of the MRYS BACT determination to Coyote may not be appropriate. MRYS uses different SO₂ control equipment (electrostatic precipitators and wet scrubbers rather than dry scrubbers with a baghouse). Pilot-scale testing is routinely performed before any SCR project proceeds. The absence of a vendor guarantee does not mean that a technology is infeasible.

S&L for Coyote: Successful operation of the tail-end configuration would also require a capital and operating cost-intensive gas-to gas heat exchanger to reheat the flue gas from approximately 200°F downstream of the existing FF to approximately 550°F to support the SCR NO_x reactions. After the flue gas passes through the SCR (at approximately 550°F), it would pass through the hot side of the gas-to-gas heat exchanger to cool the flue gas to 150°F prior to the exhaust stack. Although this stack gas temperature would be lower than the current stack temperature (190-210°F), it is still higher than the adiabatic saturation temperature of the flue gas (i.e., approximately 135°F). As such, it is likely that the existing stack could be reused without any major modifications.

Both vendors also made statements bringing into question the technical feasibility of either low-dust or tail-end SCR. For example, CERAM stated that the high levels of sodium oxide (NaO) in the ash for North Dakota lignite are not commonly found in subbituminous and bituminous coals which are fired in boilers equipped with SCR systems, and that it was unaware of any SCR application experience in the industry with the level and form of sodium in the North Dakota lignite-derived MRYS ash.

NPS: Please provide these vendor statements. Did they apply to a tail-end configuration or only to a low-dust configuration? Is there a more recent vendor statement that can be shared?

S&L for Coyote: Based in part on this information provided by SCR design engineering firms and SCR catalyst vendors, NDDEQ concluded that the use of SCR technology, including low-dust and tail-end SCR, on the lignite-fired MRYS boilers would be technically infeasible.

NPS: This is no longer entirely true. The boilers at Milton R. Young (MRYS) are cyclone boilers. NDDEQ has determined that tail-end SCR is technically-feasible on the tangentially-fired boilers at Antelope Valley Station.

S&L for Coyote: Based on a review of SCR installations on coal-fired boilers, and a review of reported advances in SCR catalysts since the first planning period, deactivation rates due to soluble alkali compounds in the flue gas (including soluble sodium and potassium compounds) remain a concern for all North Dakota lignite-fired boilers. Tail-end SCR has not been demonstrated or installed on a North Dakota lignite-fired boiler, and there are still significant technical concerns associated with the availability of existing SCR catalysts on a North Dakota lignite-fired unit. Catalyst in a tail-end SCR will still be vulnerable to alkali poisoning, pore pluggage, and premature catalyst deactivation, and it is not known whether the comparatively high levels of soluble sodium and potassium in North Dakota lignite will be effectively removed by the upstream dry FGD/FF. Furthermore, the potential exists for fine particulate remaining in the flue gas to get into the catalyst pores reducing catalyst activity. Pilot-scale studies needed to better understand catalyst deactivation mechanisms associated with high soluble alkali compound concentrations in the flue gas have not been completed.

In order to understand the effect of North Dakota lignite-derived flue gas on the tail-end SCR catalyst, identify potential design solutions, and evaluate the technical feasibility and effectiveness of tail-end SCR at Coyote Unit 1 with any degree of certainty, extended pilot scale testing of the control configuration would be needed. Additionally, because there are unresolved issues associated with catalyst poisoning, it's unlikely that OTP could obtain a viable commercial offering for tail-end SCR on Coyote Unit 1. Therefore, tail-end SCR is not an available technically feasible NO_x control technology.

NPS: A technical feasibility determination should not be based upon speculation, especially when questions can be addressed by real-world testing. Basin bears the burden of proof to show that the gas stream exiting the fabric filter would render the SCR technically infeasible and to determine the catalyst deactivation rate. Questions about catalyst deactivation could have been addressed by Basin with pilot testing on the existing system of emission controls. Because Basin did not exercise this option, tail-end SCR is presumed technically feasible.

SCR is certainly available—the question is whether it is applicable. According to the BART Guidelines:

What do we mean by “applicable” technology?

You need to exercise technical judgment in determining whether a control alternative is applicable to the source type under consideration. In general, a commercially available control option will be presumed applicable if it has been used on the same or a similar source type. Absent a showing of this type, you evaluate technical feasibility by examining the physical and chemical characteristics of the pollutant-bearing gas stream, and comparing them to the gas stream characteristics of the source types to which the technology had been applied previously. Deployment of the control technology on a new or existing source with similar gas stream characteristics is generally a sufficient basis for concluding the technology is technically feasible barring a demonstration to the contrary as described below.

What type of demonstration is required if I conclude that an option is not technically feasible?

Where you conclude that a control option identified in Step 1 is technically infeasible, you should demonstrate that the option is either commercially unavailable, or that specific circumstances preclude its application to a particular emission unit. Generally, such a demonstration involves an evaluation of the characteristics of the pollutant-bearing gas stream and the capabilities of the technology. Alternatively, a demonstration of technical infeasibility may involve a showing that there are unresolvable technical difficulties with applying the control to the source (e.g., size of the unit, location of the proposed site, operating problems related to specific circumstances of the source, space constraints, reliability, and adverse side effects on the rest of the facility).

SCR Summary

S&L: During the first planning period NDDEQ determined that high-dust SCR and tail-end SCR are not available, and thus, not a technically feasible NO_x control option for North Dakota lignite-fired boilers. The administrative record developed during the first planning period, including the BART determinations and MRYs BACT analysis, supports the conclusion that high-dust SCR and tail-end SCR are not an available NO_x control option for Coyote Unit 1. An evaluation of SCR installations and reported advances in SCR catalysts since the first planning period, coupled with the fact that high-dust SCR and tail-end SCR have not been demonstrated on a North Dakota lignite-fired boiler, and the likelihood that OTP could not obtain a viable commercial offering for tail-end SCR without extended pilot-scale testing, continues to support the conclusion that high-dust SCR and tail-end SCR are not available NO_x control technologies.

NPS: NDDEQ has determined that tail-end SCR is technically feasible on the lignite-fueled tangentially-fired boilers at Antelope Valley Station. Basin bears the burden of proof to show that tail-end SCR is not technically feasible at Coyote Unit 1. Lack of a vendor guarantee does not mean that an application of SCR is not viable or automatically eliminate consideration of SCR.

MARCH 20, 2019 LETTER FROM TERRY L. O'CLAIR, P.E., DIRECTOR, DIVISION OF AIR QUALITY TO MR. MARK THOMA, MANAGER, ENVIRONMENTAL SERVICES, OTTER TAIL POWER COOPERATIVE, RE: FOUR FACTORS ANALYSIS - COYOTE STATION

“The Department included tail-end selective catalytic reduction (SCR) as a technically feasible option in the first Regional Haze planning period. However, as you noted in your analysis, The Department ultimately determined that high dust, low dust and tail-end SCR are not technically feasible for cyclone boilers combusting North Dakota lignite (see United States of America and the State of North Dakota versus Minnkota Power Cooperative and Square Butte Power Cooperative). Table lists tail-end SCR as a technically infeasible option. Since tail-end SCR is not a technically feasible

option, we suggest that it be removed from the four-factor analysis in Tables 5-11, 6-3 and 6-4.”

MAY 10, 2019 LETTER TO MR. JIM SEMERAD, DIRECTOR, DIVISION OF AIR QUALITY, NORTH DAKOTA DEPARTMENT OF ENVIRONMENTAL QUALITY FROM MARK THOMA, MANAGER, ENVIRONMENTAL SERVICES, OTTERTAIL POWER COOPERATIVE

OTP Response: “The Four-Factor Analysis has been revised to remove tail-end SCR from Tables 5-11, 6-3, and 6-4. Portions of the text were also updated to be consistent with this change.”

– Cost of Compliance (Statutory Factor 1)

S&L for Coyote: Capital and O&M cost estimates were developed by S&L for each of the technically feasible SO₂ and NO_x control options. The Coyote Unit 1 cost estimates are conceptual in nature; thus, S&L did not procure equipment quotes specifically for the Unit 1 control system upgrades. Rather, equipment costs are based on conceptual designs developed for the retrofit control systems. Preliminary equipment sizing developed for the major pieces of equipment (based on Coyote Unit 1-specific design parameters, including typical fuel characteristics, full load heat input, and flue gas temperatures and flow rates), and recent pricing for similar equipment. S&L would characterize the cost estimates for the Coyote Unit 1 retrofit technologies as "concept screening" cost estimates generally based on parametric models, judgment, or analogy.

Fixed O&M costs include operating labor, maintenance labor, maintenance material, and administrative labor.

Variable O&M costs include the cost of consumables, including reagent, water consumption, and auxiliary power requirements. Auxiliary power requirements reflect the additional power requirements associated with the operation of the new control technology (compared to the existing technology). All O&M costs reflect the incremental increase in O&M costs compared to the costs incurred to operate the existing dry scrubber and FF control systems.

In addition to the cost effectiveness relative to the base case, the incremental cost-effectiveness to go from one level of control to the next-more-stringent level of control will also be calculated to evaluate the cost effectiveness of the more stringent control.

NPS: The Coyote four-factor analysis used spreadsheets based upon internal studies at similar facilities instead of the EPA CCM workbooks. Cost estimates in the analysis were not based upon site-specific vendor quotes or detailed engineering evaluations. The cost analysis spreadsheets contained several cost items (sales tax, owner's costs, property taxes) not included in the CCM workbooks, and applied a 20% contingency factor instead of the CCM's default 10% factor. The four-factor analysis applied a 20% contingency cost of direct and indirect capital costs to all capital cost analyses.

- The CCM says:
 - *The contingency, C, accounts for unexpected costs associated with the fabrication and installation of the absorber and is calculated by multiplying the total direct and indirect costs by a contingency factor (CF). A default value of 10% is typically used for CF.*
- Coyote four-factor analysis cost analyses applied 2% of Direct cost as Owners' Costs—this is not allowed by EPA.
- Coyote four-factor analysis cost analyses included Property Taxes = 1% of TCI. Insurance = 1% of TCI. Administration = 2% of TCI. The CCM says:
 - property taxes and overhead are both assumed to be zero, and insurance costs are assumed to be negligible. Thus, administrative charges and capital recovery are the only components of indirect annual costs estimated in this analysis.

S&L for Coyote: Capital costs and lost revenues were annualized using a capital recovery factor based on an annual interest rate of 5.25% and equipment life of 20 years.

NPS: EPA's CCM recommends a scrubber and SCR equipment life of 30 years and use of the current prime interest rate (3.25%) unless a site-specific interest rate is justified. The CCM recommends 20 years as an equipment life for SNCR.

S&L for Coyote: In an email to the North Dakota Department of Health dated December 18, 2018, EPA recommended use of a 5.25% interest rate. Otter Tail stated it does not necessarily agree that this is an appropriate percentage to use and reserves the right to update and modify this percentage at a later date. Notably, on September 26, 2018 the North Dakota Public Service Commission approved a rate of return for Otter Tail of 7.64%. This ROR represents a total weighted average cost of capital. An interest rate of 5.25% is more representative of the long-term cost of debt, which is only one component of capital structure. All O&M costs reflect the incremental increase in O&M costs compared to the costs incurred to operate the existing dry scrubber and FF control systems.

NPS: We used the 5.25% interest rate for Coyote in our calculations due to its PUC filings.

– Economic Evaluation - SO₂ Controls

NPS: Even with the factors that inflated costs, noted above, the average and incremental cost effectiveness of replacing the old scrubber at Coyote would be acceptable in the context of the previous ND BART thresholds as well as the thresholds used by the states cited. Table 2 below (NDDEQ's Table 9) shows that all of the options evaluated, except for the WFGD, are reasonably cost-effective.

Table 2.(NDDEQ draft SIP, Table 9) SO₂ Cost of Compliance and Incremental Cost of Compliance for Coyote Unit 1

Control Technology	Performance Rate (lb/MMBtu)	Annual Emission Reduction (tpy)	Annualized Total Cost (\$)	Cost of Compliance (\$/ton)	Incremental Cost of Compliance (\$/ton)
DFGD/FF (Baseline)	0.85				
DSI + Existing FGD	0.58	4,118	12,371,000	3,004	
FGD Improvements	0.50	5,338	2,085,000	391	-8,431
DSI + FGD Improvements	0.33	7,930	14,456,000	1,823	4,772
Absorber Replacement	0.09	11,590	21,122,000	1,822	1,821
WFGD	0.06	12,048	49,094,000	4,075	61,139

We revised S&L's cost estimates for the absorber replacement option to eliminate owner's costs and property taxes, reduce the contingency cost, and revise the capital recovery cost to reflect a 30-year scrubber life.

Table 3. NPS Revised SO₂ Cost of Compliance and Incremental Cost of Compliance for Coyote Unit 1

Control Technology	Performance Rate (lb/MMBtu)	Annual Emission Reduction (tpy)	Annualized Total Cost (\$)	Cost of Compliance (\$/ton)	Incremental Cost of Compliance (\$/ton)
DSI + FGD Improvements	0.33	7,930	14,456,000	1,823	4,772
Absorber Replacement	0.09	11,590	17,338,329	1,496	788

Replacement of the existing dry scrubber could reduce SO₂ emissions by almost 11,600 tons/year versus baseline emissions.

– Time Necessary for Compliance (Statutory Factor 2)

NDDEQ: A summary of anticipated timelines for installation of controls is provided in Table 10.

Table 4. (NDDEQ draft SIP, Table 10) Time Required for SO₂ Controls

Control Technology	Total time after SIP approval (months)
DSI + Existing FGD	18
FGD Improvements	0
DSI + FGD Improvements	18
Absorber Replacement	32

– Energy and Non-Air Quality Environmental Impacts (Statutory Factor 3)

ENERGY

NDDEQ: Small changes to onsite energy consumption are likely to be experienced with the implementation of any SO₂ control options. The impacts are not significant enough to eliminate and SO₂ controls as viable control options.

NON-AIR QUALITY ENVIRONMENTAL IMPACTS

NDDEQ: Similar to the energy impacts for SO₂ controls, any non-air quality environmental impacts are not significant enough to eliminate additional SO₂ controls as a viable option.

– Remaining Useful Life (Statutory Factor 4)

NDDEQ: Based on the information provided to the Department, Coyote is expected to operate beyond the life of the control equipment. Therefore, remaining useful life was not considered.

Economic Evaluation - NO_x Controls

NDDEQ: The cost of compliance and incremental cost for the reasonable progress controls are listed in Table 6.

Table 5. (NDDEQ draft SIP, Table 6) NO_x Cost of Compliance and Incremental Cost of Compliance for Coyote Unit 1

Control Technology	Performance Rate (lb/MMBtu)	Annual Emission Reduction (tpy)	Annualized Total Cost (\$)	Cost of Compliance (\$/ton)	Incremental Cost of Compliance (\$/ton)
SOFA (Baseline)	0.46				
SOFA Optimization	0.42	610	0	0	
SNCR + Optimization	0.28	2,745	4,753,933	1,732	
SNCR + RRI + Optimization	0.20	3,965	12,690,135	3,200	6,505

A detailed breakdown of the costs listed in NDDEQ draft SIP, Table 6 (Table 5 above) can be found in Coyote's submitted four factors analysis. The Department has reviewed these costs and believes them to be accurate.

As displayed in NDDEQ Table 6 (Table 5 above) and stated in Section 3.1.1, there is no cost associated with optimization of the combustion process. The 0.04 lb NO_x per MMBtu improvement over the baseline performance would be required as the first step for any of the remaining technologies evaluated.

If SNCR is installed in conjunction with combustion optimization, a performance rate improvement of 0.18 lb NO_x per MMBtu could be achieved. This equates to a potential reduction of approximately 2,750 tons NO_x per year from the baseline emissions. Fiscally, SNCR

installation requires an estimated annualized cost of \$4.75 million and NO_x removal cost of roughly \$1,700 per ton.

The addition of RRI to SNCR and combustion optimization results in an expected performance improvement of 0.26 lb NO_x per MMBtu from the baseline performance rate. This equates to a potential reduction of approximately 3,970 tons NO_x per year from the baseline emissions. Fiscally, SNCR + RRI installation requires an estimated annualized cost of \$12.7 million and NO_x removal cost of \$3,200 per ton. To determine the appropriate reasonable progress control selection between SNCR and SNCR + RRI, the Department determined the stand-alone cost of installing RRI after SNCR is installed. This stand-alone cost is referred to as the incremental cost of compliance. Incremental cost of compliance is a key factor to consider when selecting reasonable progress controls since it details the cost effectiveness of RRI installation. A cost breakdown indicates approximately \$8 million of the annualized cost is attributable to the installation of RRI, and results in the potential for an additional 1,220 tons of NO_x to be removed. This results in an incremental cost of compliance of roughly \$6,500 per ton.

NPS: We added estimates for SCR based upon the CCM workbook. Our estimate that SCR on Coyote Unit 1 can achieve 0.05 lb/mmBtu is consistent with demonstrated SCR emission rates and does not exceed 90% efficiency.

Table 6. NPS Revised NO_x Cost of Compliance and Incremental Cost of Compliance for Coyote Unit 1

Control Technology	Performance Rate (lb/MMBtu)	Annual Emission Reduction (tpy)	Annualized Total Cost (\$)	Cost of Compliance (\$/ton)	Incremental Cost of Compliance (\$/ton)
SOFA (Baseline)	0.46				
SOFA Optimization	0.42	610	0	0	
SNCR + Optimization	0.28	2,745	4,753,933	1,732	
SNCR + RRI + Optimization	0.20	3,965	12,690,135	3,200	6,505
SCR	0.05	5,684	13,778,780	2,424	633

Addition of RRI to Optimized SNCR could reduce NO_x emissions by almost 4,000 tons/year versus baseline emissions. Addition of SCR could reduce NO_x emissions by almost 5,700 tons/year versus baseline emissions.

– Time Necessary for Compliance (Statutory Factor 2)

A summary of the anticipated timelines for the installation of controls is provided in NDDEQ Table 7 (Table 7 below).

Table 7.(NDDEQ draft SIP, Table 7) Time Required for NO_x Controls

Control Technology	Total time after SIP approval (months)
SOFA Optimization	0
SNCR + Optimization	22
SNCR + RRI + Optimization	22

– Energy and Non-Air Quality Environmental Impacts (Statutory Factor 3)

ENERGY

Small changes to onsite energy consumption are likely to be experienced with the implementation of any add-on NO_x controls.⁵ The impact not significant enough to eliminate add-on NO_x controls as a control option.

NON-AIR QUALITY ENVIRONMENTAL IMPACTS

SNCR use ammonia as a reagent. Ammonia slip emissions will result in the flue gas stream on the exhaust side of the control equipment due to the operation of the SNCR (~10 ppm). The ammonia slip emissions from the operation of SNCR would likely combine with the dry FGD solids. The ammoniated dry FGD solids would require that further safety precautions are taken for Coyote staff who perform maintenance on the ash handling system or staff who dispose of waste.

Similar to the energy impacts for add-on NO_x controls, the non-air quality environmental impacts are not significant enough to eliminate add-on NO_x controls as a control option.

– Remaining Useful Life (Statutory Factor 4)

Based on the information provided to the Department, Coyote is expected to operate beyond the life of the control equipment. Therefore, remaining useful life was not considered.

3.1.5 Conclusions & Recommendations

- Other states have set cost-effectiveness thresholds of: \$5,000/ton for EGUs in AR and TX, \$7,000/ton in NM, and \$10,000/ton in CO and OR.
- The cost effectiveness of replacing the old scrubber at Coyote would be acceptable in the context of the previous ND BART thresholds as well as the thresholds used by the states cited. Replacement of the existing dry scrubbers with modern new scrubbers could cost-effectively reduce facility SO₂ emissions by almost 11,600 tons/yr.
- The annual average cost effectiveness of adding SNCR + RRI at Coyote would be acceptable in the context of the previous ND BART thresholds as well as the thresholds used by the states cited. Addition of SNCR + RRI could reduce facility NO_x emissions by almost 4,000 tons/yr.

- The average cost effectiveness of adding SCR at Coyote would be acceptable in the context of the previous ND BART thresholds as well as the thresholds used by the states cited. Addition of SCR could reduce facility NO_x emissions by almost 5,700 tons/yr.

3.2 Antelope Valley Station

3.2.1 Summary of NPS Recommendations and Requests for Antelope Valley

NPS review of the four-factor analysis conducted for Antelope Valley Station (AVS) finds that there are technically feasible and cost-effective opportunities available to further control SO₂ and NO_x emissions from Units 1 and 2. In fact, we find that the cost of control is more economical than estimated when analyses are adjusted in accordance with the EPA Cost Control Manual.

Although ND has not established a cost threshold for this round of regional haze planning, we can advise that other states have set cost-effectiveness thresholds of: \$5,000/ton for EGUs in AR and TX, \$7,000/ton in NM, and \$10,000/ton in CO and OR.

The incremental cost effectiveness of replacing the existing SO₂ scrubbers at AVS would be acceptable in the context of the previous ND BART thresholds as well as the thresholds used by the states cited. Replacement of the existing dry scrubbers with modern new scrubbers could cost-effectively reduce facility SO₂ emissions by over 10,000 tons/yr.

We find SNCR and SCR opportunities for reducing NO_x emissions at AVS. 1) Addition of SNCR would be cost effective in the context of the previous ND BART thresholds as well as the thresholds used by other states in this round of RH SIP planning. SNCR at AVS Units 1 and 2 and could reduce facility NO_x emissions by 700 tons/yr. 2) The average cost effectiveness of adding SCR at Coyote would meet the cost thresholds used by CO and OR. Addition of SCR could reduce facility NO_x emissions by over 2,300 tons/yr.

We recommend that ND take every opportunity to reduce SO₂ and NO_x emissions from the Antelope Valley Station in this planning period. By requiring implementation of identified controls ND will be reducing haze causing emissions and advancing incremental improvement of visibility at Theodore Roosevelt, Badlands, and Wind Cave National Parks as well as other Class I areas in the region.

3.2.2 Plant Characteristics

AVS is a 954 MW power station owned and operated by Basin Electric Power Cooperative (Basin) near Beulah, North Dakota. Theodore Roosevelt National Park, an NPS Class I area, is 109 km west of this facility.

Of 1,167 facilities in EPA's Clean Air Markets Database (CAMD) in 2020, AVS ranked #15 for SO₂ emissions (11,316 tons) and #64 for NO_x emissions (3,496 tons). AVS' carbon dioxide emissions of 6,876,033 tons rank #49 in the US. AVS also ranked #7 for EGU mercury (Hg) emissions with 183 lb in 2017.

AVS has two generating units (Units 1 and 2) each rated at 477 megawatts (MW). AVS Unit 1 went on-line in 1984 and Unit 2 in 1986. AVS Units 1 and 2 are Combustion Engineering (CE) subcritical pulverized coal (PC), tangential-fired units firing North Dakota lignite. Unit 1 and Unit 2 each have a heat input capacity of 6,275 MMBtu per hour. AVS receives a majority of its lignite fuel from the fine coal rejected by the adjacent Great Plains Synfuels Plant (GPSP) coal screening process, with the balance of fuel requirements being delivered directly to AVS from the Freedom Mine, which is located adjacent to the AVS/GPSP Complex.

Each unit has the same control equipment. NO_x emissions are controlled by a separated over-fire air (SOFA), Low-NO_x Concentric Firing System (LNCFS), and Omnivise Combustion Optimizer. SO₂ and PM emissions are controlled by a dry lime flue gas desulfurization (DFGD) system, and fabric filter baghouse (FF) control system. . Mercury emissions are controlled by a sorbent injection system to comply with the Mercury and Air Toxics Standards.⁸ The Table 8 below shows a breakdown of 2020 SO₂ and NO_x emissions and how they rank versus the 3,317 EGUs in CAMD.

Table 8. Antelope Valley Station 2020 SO₂ and NO_x emissions and rank out of 3,317 EGUs in CAMD

Unit ID	Gross Load (MW-h)	SO ₂ (tons)	SO ₂ (tons) Rank	Avg. SO ₂ Rate (lb/MMBtu)	Avg. SO ₂ Rate (lb/MMBtu) Rank	Avg. NO _x Rate (lb/MMBtu)	Avg. NO _x Rate (lb/MMBtu) Rank	NO _x (tons)	NO _x (tons) Rank
B1	2,989,552	5,420	34	0.367	109	0.1148	671	1,702	120
B2	3,084,092	5,896	31	0.351	118	0.1074	721	1,794	111

3.2.3 First Planning Period Reasonable Progress Control Requirements for AVS Units 1 and 2

AVS Units 1 and 2 were not subject to the Regional Haze BART requirements of 40 CFR 51.208(e). Nevertheless, during the initial planning period NDDEQ evaluated emissions reductions from AVS as a Reasonable Progress⁹ (RP) source. Based on an evaluation of control technology costs and the resulting incremental improvement in visibility, NDDEQ found that no additional NO_x controls were warranted during the initial planning period.

On September 21, 2011, EPA published a proposed rule to partially approve and partially disapprove specific aspects of the North Dakota Regional Haze SIP.¹⁰ Among other things, EPA proposed to disapprove the state's reasonable progress determination for AVS Units 1 and 2. EPA proposed the promulgation of a Federal Implementation Plan (FIP) which included a

⁸ January 2021 Hg emissions were: Unit 1= 2.92 lb/Trillion Btu (TBtu), Unit 2 = 2.52 lb/TBtu.

⁹ The Regional Haze Rule (RHR) requires states to demonstrate the progress made to date and determine any additional progress needed to achieve the visibility improvement goals established for this planning period. States are required to set Reasonable Progress goals which 1) must provide for an improvement in visibility for the most impaired days over the period of the implementation plan and 2) ensure no degradation in visibility for the least impaired days over the same period.

¹⁰ 76 Fed. Reg. 58570, September 21, 2011 (the "Proposed FIP").

reasonable progress determination and NO_x emission limits for AVS Units 1 and 2. EPA proposed low-NO_x burners (LNB) plus SOFA and an emission limit of 0.17 lb/MMBtu (30-day rolling average) for reasonable progress NO_x control on AVS Units 1 and 2.¹¹

EPA issued its final rule on April 6, 2012.¹² With respect to NO_x control on AVS Units 1 and 2, EPA finalized its proposed determination that LNB+SOFA and a NO_x emission rate of 0.17 lb/MMBtu (30-day rolling average) was required for reasonable progress. North Dakota challenged EPA's disapproval of its reasonable progress determination for AVS Units 1 and 2, and EPA's subsequent promulgation of the FIP. The District Court found that EPA's determination on this matter was entitled to judicial deference, and could not conclude that EPA acted in a manner that was arbitrary or capricious; therefore, the state's petition for review was denied and EPA's reasonable progress determination for AVS Units 1 and 2 was upheld.

The FIP required Basin to install the NO_x control technologies on AVS Units 1 and 2 by July 31, 2018. In accordance with the FIP requirements, Basin installed a low-NO_x concentric firing system (LNCFS) on AVS Units 1 and 2 in 2014 and 2016, respectively, coinciding with the scheduled tri-annual maintenance outages.

The NDDEQ has submitted a SIP revision for AVS, which would replace the FIP. On March 12, 2021 EPA proposed to approve the SIP revision submitted by the NDDEQ on August 3, 2020 which adopted the FIP requirements. In conjunction with this proposal, EPA also proposed to withdraw the portions of the 2012 FIP which applied to AVS.

2020 fuels data from the Energy Information Administration shows the average sulfur content of the lignite burned at AVS would result in uncontrolled SO₂ emissions of 2.08 lb/mmBtu.¹³ CAMD data for AVS in 2020 showed that controlled SO₂ emissions averaged 0.367 lb/mmBtu. The average annual SO₂ removal efficiency was 82%–83%. The charts below show SO₂ and NO_x emissions for the AVS units.

¹¹ Id. at pg. 58632. EPA: We have eliminated higher performing options—SNCR + LNB, SCR, and SCR + LNB—because their cost-effectiveness values are significantly higher and/or the emission reductions are not that much higher than LNB. Considering the statutory factors, we find that it is not reasonable to insist on these higher control levels in this first planning period. However, we expect the State to consider such controls in the next planning period.

¹² 77 Fed. Reg. 20894.

¹³ Average sulfur content was 0.91% with an average heat content of 13.154mmBtu/ton.

3.2.4 Second Planning Period Reasonable Progress Control Requirements for AVS Units 1 and 2

NDDEQ: NDDEQ sent a letter to Basin on May 2, 2018 requesting a four factors analysis¹⁴ (4FA) for AVS. The letter required that the four factors analysis be submitted to the NDDEQ on or before January 31, 2019.

In January 2019, Sargent & Lundy LLC (S&L) prepared a 4FA for the AVS on behalf of Basin.¹⁵ The analysis included an assessment of potentially available SO₂ and NO_x emission reduction technologies for AVS Unit 1 and 2.

NDDEQ provided comments to Basin regarding Basin’s 4FA on June 20, 2019: “The design sulfur emission rate should be reevaluated and appropriate revision to the analysis made.” Basin submitted a response to the NDDEQ’s comments on July 12, 2019:

Although S&L used an uncontrolled SO₂ rate of 3.39 lb/MBtu as the design basis for the Four-Factor Analysis, that value was only used for the Projected Future Maximum Case. Uncontrolled SO₂ rates of 2.90 lb SO₂/MBtu for Units 1 and 2 (see Table 4-4 of the Four Factor Analysis) were used for the Actual Average Case...We agree that the existing DFGD alone may provide a removal efficiency of approximately 82-83%,

¹⁴ 42 U.S. Code § 7491. Visibility protection for Federal class I areas

(g) Definitions For the purpose of this section—

(1) in determining reasonable progress there shall be taken into consideration the costs of compliance, the time necessary for compliance, and the energy and nonair quality environmental impacts of compliance, and the remaining useful life of any existing source subject to such requirements;

¹⁵ Basin’s original four-factor analysis was submitted to the Department on January 31, 2019.

Based on the information reviewed, future operations and emissions profiles are expected to remain consistent with current conditions.

NPS: Following are excerpts from the January 2019 S&L report—we note where we have differences.

SO₂ Emissions Controls

– Technical Feasibility of Available SO₂ Control Options

FUEL SWITCHING

AVS is a mine mouth generation facility. AVS was designed and developed to burn North Dakota lignite coal received from the adjacent Freedom Mine for the purpose of generating electricity. Previous regulatory and court decisions have concluded that requiring a mine mouth facility to evaluate low sulfur coal would require the facility to redefine its fundamental purpose and design; therefore, fuel switching can be rejected as an available control option. Because the use of North Dakota lignite from the adjacent Freedom Mine is an inherent aspect of AVS operation, fuel switching will not be evaluated.

EXISTING FGD OPERATIONAL IMPROVEMENTS AND EQUIPMENT UPGRADES

Operational and other design changes/upgrades to the existing dry scrubber may provide an opportunity for additional SO₂ removal and allow the units to achieve lower controlled SO₂ emissions. S&L, working with Basin Electric personnel on behalf of AVS, identified a number of potentially feasible operational changes that may be available to increase SO₂ removal efficiency with the existing equipment. A detailed discussion of each of these options is provided in the following sections.

Station Work Practices

AVS Units 1 and 2 have a 3-hour SO₂ plantwide applicability limit (PAL) of 3,845 lb/hr in their Title V Air Permit that allows the station to adjust operation of each unit's FGD system as long as they achieve the overall plantwide limit. Historically, when one unit was in extended major outage the station would adjust operation (i.e., decrease SO₂ removal) on the other Unit to be in compliance with the PAL. AVS schedules major maintenance outages on a tri-annual (three-year) basis. As such, the opportunity for additional reductions is available one out of every 3 years on each unit. S&L reviewed the operating practices of the two units over the period June 2015–June 2018 to determine the increase in SO₂ emissions for the unit that was not in outage. The excess emission on Units 1 and 2 were 472 tons and 396 tons, respectively on an annual basis. Using the annual baseline SO₂ emissions and annual average heat input, eliminating these emissions would reduce the outlet SO₂ emission rate from 0.37 lb/MMBtu to a controlled emission rate of 0.35 lb/MMBtu on each Unit. However, it should be noted that under the current outage schedule, the emission reductions would only be achieved every 3rd year for a single unit since outages occur on a tri-annual basis. Based on this analysis, a change to the current station work practice is considered a technically feasible SO₂ control option for AVS Units 1 and 2.

Lime Quality

Based on a review of lime analyses and a review of operating data from the existing lime slaking system, AVS currently procures a high-quality lime for use in the dry scrubbers. The typical CaO content of the lime used at AVS is 90% or greater, and the slaking process achieves a 40°C temperature rise within three minutes of adding water. For these reasons, changing the lime quality is not considered a technically feasible operational change available to control SO₂ emissions from AVS, and will not be evaluated further.

Ca:S Stoichiometric Ratio

Other operational changes that may be available to increase the Ca:S stoichiometry in the existing dry scrubber include: (1) increasing the byproduct recycle ash rate; and/or (2) increasing the quantity of fresh hydrated lime introduced to the system. Due to the cost savings that may be realized with the first option, some facilities with existing DFGD controls have opted to increase solids recycle rates to as high as 40-50% solids to achieve an incremental increase in SO₂ reduction, if capacity was available in the byproducts handling system. If capacity is not available, increasing fresh lime addition to the system may also be a viable option to increase the Ca:S stoichiometric ratio.

Within each AVS DFGD, there are two parallel slurry preparation trains that prepare and supply the lime slurry feed to each of the five scrubber modules. The slurry preparation trains consist of recycle ash silos, ash mix tanks, slurry feed tanks and associated slurry and atomizer feed pumps, piping and controls and instrumentation. Solids from a dry scrubber consist of fly ash, reaction byproduct, and residual unreacted hydrated lime. On AVS Units 1 and 2, solids collected in the fabric filter hoppers are conveyed to either a dry storage silo for disposal or to a recycle ash silo where it is used as reactant slurry. The recycle system is designed to utilize a portion of the unreacted lime in the solids rather than disposing of all of the solids. Recycle solids are combined with the fresh lime addition to provide the makeup lime needed for SO₂ reduction. Increasing the recycle rate can increase the amount of available Ca added to the system (i.e., stoichiometric ratio) without increasing the quantity of fresh lime added to the system.

The DFGD systems on the AVS Units currently operate the recycle system at approximately 45% solids. The AVS recycle system is operating within the original design conditions and system capacity which is in line with industry practice. The plant has tested higher recycle rates, but at these higher rates plant personnel reported significant problems with recycle slurry pumping and pluggage of the recycle tanks and negative impacts to the fabric filter due to the increase in ash loading. Based on the adverse operational impacts observed during these tests, increasing the recycle percent solids is not considered a technically feasible SO₂ control option for the AVS Units, and will not be evaluated further.

As an alternative to increasing the recycle rate, the Ca:S stoichiometric ratio in the system may be increased by increasing the quantity of fresh lime introduced to the system. Basin Electric contracted with B&W, the original equipment manufacturer (OEM) of the AVS DFGD system, to determine if additional SO₂ removal could be achieved by increasing the amount of fresh lime added to the system while maintaining approximate 40-45% solids slurry to the atomizer. B&W ran their proprietary software which estimates the AVS DFGD performance. The results of the model indicated that AVS could potentially achieve 93% SO₂ removal of normal DFGD

operation at 1% sulfur coal by increasing the fresh lime to the DFGD. Due to the uncertainties with the model, additional analysis is required to fully understand plant operational and performance impacts associated with an increased Ca:S stoichiometric ratio. There would be percent solids capacity limitation with the existing recycle slurry system and risks of increased scaling and build-up within tanks and piping with the increased lime solids. As such, this system will require modifications including new mix tanks, pumps and piping to minimize slurry preparation train outages. When a slurry preparation train fails, it requires the standby slurry preparation train to come on-line that could result in an increase in short term emissions until the slurry preparation train is placed into service. The 93% removal represents an average percent control that each AVS unit would be expected to achieve on an on-going long-term basis under normal operating conditions with the equipment upgrades installed. The emission rate should not be construed to represent proposed permit limits. Corresponding permit limits must be evaluated on a control system-specific basis.

Approach to Saturation Temperature

The AVS dry scrubbers currently operate with at an outlet temperature near 165-170°F, which is approximately 30°F above the adiabatic saturation temperature and within the OEM design. This is in line with new spray dryer absorbers which are typically designed to operate at 30°F approach to saturation. Therefore, the current approach to saturation temperature achieved on the AVS scrubbers are aligned with standard industry practices. Lowering the outlet temperature further has significant potential to cause detrimental corrosion of the vessel or downstream equipment and other significant operating issues. Therefore, further reducing the absorber module outlet temperature is not considered a technically feasible SO₂ control option for AVS, and will not be evaluated further.

Atomizer Replacement

AVS Units 1 and 2 dry scrubbers were provided by B&W's predecessor Joy Niro, and were designed with five absorber modules each with a single rotary atomizer with a 12-nozzle wheel to achieve a fine slurry spray. The design of the atomizer and speed at which the wheel rotates are controlling factors for the size and form of the droplets in the spray. Each atomizer wheel in AVS Unit 1 absorber module is powered by a 700 hp motor and Unit 2 absorber modules are designed with a 800 hp motor. In addition, the design of the atomizers is highly dependent on the spray pattern needed to mix with the hot flue gas in the scrubber module for optimum absorption of SO₂ while also preventing wetting of the absorber walls. Based on S&L's analysis and input from the station, there has not been any significant moisture carry-over into the baghouse or wetting of the absorber walls that would indicate that the atomizers are not achieving an optimum droplet size or spray pattern. In addition, both AVS dry scrubbers are operating at a consistent 30°F approach to saturation temperature, in-line with industry practice, concluding that the droplets are drying efficiently. Therefore, replacing the atomizer motor or atomizer wheel is not considered a technically feasible SO₂ control option for the AVS scrubbers, and will not be evaluated further.

Slaker Replacement

Lime slurry, the reagent used for SO₂ removal in a dry scrubber, is produced by mixing pebble lime with heated water in a slaker; this process is referred to as “slaking”. The slaker is operated at an optimum water-to-lime ratio (typically between 3:1 and 6:1) to produce lime slurry by metering the amount of water and the amount of lime added to the slaker. Slakers are typically designed to produce a lime slurry between 15-20% solids. The lime slurry is added to the recycle slurry in a mix tank and then sent to the atomizer where it is sprayed into the scrubber for SO₂ removal.

In 2011, additional slaking capacity was installed at a cost of approximately \$15 million, in the form of two Vert-Mill lime slakers, lime storage and conveying systems in preparation of higher sulfur fuel deliveries. The slakers operate at a 5:1 water to lime ratio and approximately 18% solids which is in line with the design as well as industry practice. Therefore, replacing the already upgraded slaking systems is not considered a technically feasible SO₂ control option for the AVS scrubbers, and will not be evaluated further.

Adding an Absorber Module

Another option for extending the residence time within the reactor modules and increasing Ca:S contact would be to add an additional reactor module to each AVS unit. The existing system is designed with five absorber modules per unit. The system was originally designed to operate with four modules carrying full load gas flow with a standby spare available for routine maintenance. Subsequently, operation was changed so that all five modules are operated for full load gas flow. This change increased flue gas residence time in the reaction vessels from 5.0 seconds (at full load) to 6.5 seconds. More recent dry scrubbing systems have been designed with reaction vessel residence times of 10 seconds or more.

One potential option available to AVS to further increase reaction vessel residence time would be to add an additional absorber module to the existing dry scrubbing system on each unit. The number of absorber modules used in a DFGD system is dependent on multiple operating parameters, including the flue gas flow rate and SO₂ concentrations. DFGD modules are typically specified with minimum and maximum flue gas flow rates. If the absorber modules are oversized, flue gas velocities through the module can be too low, causing solids dropout inside the vessel. If the absorber modules are undersized, flue gas velocities can be too high, causing residence time to fall below recommended levels.

Dry scrubbing units that are operating at flue gas volumes significantly above the design flow rate can benefit from adding an extra module to the system. The module would be placed in parallel with the existing modules to achieve a similar pressure drop through each vessel and to ensure equal flue gas distribution to the modules. In 2006, Basin Electric hired B&W's Allen-Sherman Hoff to develop a computer model of the existing five scrubber modules to determine the impact of adding a 6th absorber module to each of the AVS units in response to potentially higher-sulfur fuels in the future. The modeling showed the five existing absorbers have adequate residence time for the expected higher sulfur in the coal and operate at an approach to saturation of 30°F which is consistent with industry practice. Installation of a sixth absorber would not provide any significant improvement towards removing additional sulfur. The primary benefit of

a sixth SDA chamber would be to provide redundancy. While this would be beneficial towards maintaining unit loads without having to restrict generating capacity for chamber maintenance items, inspections and chamber cleaning, it would not provide any additional improvement to reducing SO₂. Therefore, incorporating an additional absorber module into the existing system is not a technically feasible SO₂ control strategy for AVS, and will not be evaluated further.

Replacing Existing Absorbers with New Absorber Modules

Replacing the existing modules with new absorber modules would require significant engineering and facility modifications. Based on a preliminary review of the control system layout, the only practical location for this option would be to construct the new vessels in the same location as the existing modules. Locating the DFGD modules adjacent to the existing dry scrubber would require flue gas to be redirected from the air heater outlet to the new absorbers and back to the existing fabric filter, which would likely result in significant solids dropout and other operational issues. Therefore, locating the new absorber modules adjacent to the existing absorber modules is not considered a technically feasible option.

DFGD control systems use a hydrated lime slurry to remove SO₂ from the combustion gases. Various operating parameters will affect the efficiency of the DFGD process including the residence time and how close the system operates to saturation. These are the same operating parameters that affect the efficiency of the existing AVS Units 1 and 2 dry scrubbers. The AVS Units 1 and 2 dry scrubbers already operate at an approach to saturation temperature of 30°F which is consistent with industry practice as well as have adequate residence time. Therefore, replacing the existing absorber modules with new absorber modules would not provide any additional benefit and will not be evaluated further.

EXISTING FGD + DRY DSI

DSI upstream of the existing dry scrubber is a technically feasible and commercially available SO₂ control option for AVS Units 1 and 2. Taking into consideration the fact that AVS is currently equipped with a calcium-based dry scrubbing system, hydrated lime dry DSI would be the most practical, and potentially the most effective, DSI control option. Sodium-based systems would require extensive testing to determine the potential impacts associated with introducing significant quantities of sodium into the existing system, and are not considered practical control options for AVS Units 1 and 2. However, although DSI is a technically feasible control option, it should be noted that DSI upstream of the existing DFGD control system at AVS would not provide any additional SO₂ removal than what could already be achieved by increasing the fresh lime or calcium content through the existing upgraded lime slaking system as discussed in Section 4.3.2.2 Ca:S Stoichiometric Ratio. The existing upgraded lime slaking system at AVS has sufficient capacity to provide the increase in calcium content. Therefore, DSI will not be evaluated further.

RETROFIT NEW DRY FGD SYSTEM

Replacing the existing dry scrubber/FF with new control systems would require significant engineering and modifications to the facility. Based on a preliminary review of the facility layout, the new control systems could be located south of Unit 1 and north of the Unit 2 existing

dry scrubber/FF. The new DFGD/FF and all auxiliary equipment could be constructed while the units remain on-line. The control systems could be tied-in to the existing systems during a scheduled major outage.

Spray Dryer Absorber / Fabric Filter

Replacing the existing dry scrubber/FF with a new SDA/FF control systems is a technically feasible and commercially available control option on the AVS Units. SDA/FF control systems are generally limited to an SO₂ removal of approximately 95%. This removal represents what the control system vendor would be willing to guarantee upon initial operation of the control system.

Circulating Dry Scrubber / Fabric Filter

A second type of dry scrubbing system is the circulating dry scrubber (CDS). Similar to other DFGD systems, the CDS system would be located after the air preheater, and byproducts from the system collected in an integrated fabric filter. Unlike the SDA systems, CDS systems use a circulating fluidized bed of hydrated lime reagent to remove SO₂ rather than an atomized lime slurry; however, similar chemical reaction kinetics are used in the SO₂ removal process.

As with the SDA/FF option, replacing the existing DFGD with a new CDS/FF control system would require significant engineering and modifications to the existing facility. For this evaluation it was assumed that the CDS/FF control systems could be located adjacent to the existing dry scrubber/FF, and that the control systems could be tied-in to the existing system during a scheduled major outage.

Replacing the existing dry scrubber and FF with a new CDS/FF control system is a technically feasible and commercially available control option for the AVS units. Based on engineering judgment, it is anticipated that the retrofit CDS/FF control option would achieve controlled SO₂ emission rates higher than those achieved with a SDA/FF due to the increased Ca:S in the fluidized bed absorber vessel. Based on recent CDS retrofit projects, and taking into consideration expected future design coal characteristics, it is anticipated that the retrofit CDS/FF control system could achieve SO₂ removal efficiencies of approximately 97%. This removal efficiency represents what the control system vendor would be willing to guarantee upon initial operation of the system and on an ongoing long-term basis under normal operating conditions.

RETROFIT NEW WET FGD SYSTEM

Another option available to AVS would be to replace the existing dry scrubbing system with a new wet FGD control system located downstream of the existing FF.

Wet Limestone Scrubbing

For this evaluation, it was assumed that the existing AVS dry scrubber reactor vessel would remain in place, and that the WFGD control system would be located downstream of the existing FFs and ID fans most likely south of Unit 1 and north of the Unit 2 existing dry scrubber/FF. Dry scrubber reactor vessel internals would ultimately be removed to reduce pressure drop through the system. A single absorber tower for each Unit would be sufficient for the flue gas flow. In addition to the absorber tower and reaction vessel, the WFGD control system would require a

limestone handling and preparation system and by-product dewatering systems. Because of the saturated nature of the flue gas exiting the WFGD and the velocity requirements with wet stack operation, a new stack with a liner capable of wet flue gas operation would be required. New booster ID fans would also be required to account for the additional pressure drop through the WFGD control system.

Wet FGD technology is an established SO₂ control technology. Wet scrubbing systems have been installed on units that fire medium to high sulfur coals, and would be a technically feasible SO₂ control option for AVS Units 1 and 2. Based on engineering judgment and information from control system vendors, it is anticipated that a retrofit WFGD control system on a North Dakota lignite-fired unit would be designed to achieve an SO₂ removal efficiency of approximately 98%. This removal efficiency represents what the control system vendor would be willing to guarantee upon initial operation of the system and on an on-going long-term basis under normal operating conditions.

– Cost of Compliance (Statutory Factor 1)

S&L for AVS: Capital costs and lost revenues were annualized using a capital recovery factor based on an annual interest rate of 5.25% and equipment life of 20 years.

NPS: EPA's Control Cost Manual (CCM) recommends use of the current prime interest rate of 3.25% and equipment life of 30 years.

S&L for AVS: Capital and O&M cost estimates were developed for each of the technically feasible SO₂ control options. The AVS Units 1 and 2 cost estimates are conceptual in nature; thus, S&L did not procure equipment quotes specifically for the Units 1 and 2 control system upgrades. All O&M costs reflect the incremental increase in O&M costs compared to the costs incurred to operate the existing dry scrubber and fabric filter control systems.

NPS: S&L used spreadsheets based upon internal studies at similar facilities to estimate costs, these cost estimates were not based upon site-specific vendor quotes or detailed engineering evaluations. The S&L spreadsheet contained several cost items (sales tax, owner's costs, property taxes) not included in the CCM workbooks, and applied a 20% contingency factor instead of the CCM's default 10% factor. We applied the CCM workbook for wet and dry scrubbers as described below.

We applied the CCM "Wet and Dry Scrubbers for Acid Gas Control" workbook to the existing SDA scrubbers based upon 2020 EIA fuels data and the most-recent five years of CAMD data. We estimated that the current SDA scrubbers have a direct annual cost of \$12– \$13 million which would end if the scrubbers are replaced. The costs of the new replacement 98% efficient wet FGD and new 97% efficient CDS were also estimated using the CCM workbook; results are tabulated below.

Table 9. NPS Revised NDDEQ Table 9: AVS Unit 1 SO₂ Cost of Compliance and Incremental Cost of Compliance

Control Technology	Performance Rate (lb SO ₂ /MMBtu)	Annual Emission Reduction (tpy)	Annualized Total Cost (\$)	Cost of Compliance (\$/ton)	Incremental Cost of Compliance (\$/ton)
DFGD/FF (Baseline)	0.36				
Station Work Practice	0.35	174	135,000	775	
Ca:S Stoichiometry	0.2	2,788	1,938,773	695	690
DFGD (CDS/FF)	0.06	4,986	14,066,450	2,821	5,518
WFGD	0.04	5,316	15,811,967	2,974	5,278

Table 10. NPS Revised NDDEQ Table 9: AVS Unit 2 SO₂ Cost of Compliance and Incremental Cost of Compliance

Control Technology	Performance Rate (lb SO ₂ /MMBtu)	Annual Emission Reduction (tpy)	Annualized Total Cost (\$)	Cost of Compliance (\$/ton)	Incremental Cost of Compliance (\$/ton)
DFGD/FF (Baseline)	0.36				
Station Work Practice	0.35	174	135,000	775	
Ca:S Stoichiometry	0.2	2,788	1,938,773	695	690
DFGD (CDS/FF)	0.06	4,699	14,407,153	3,066	6,526
WFGD	0.04	5,038	16,167,853	3,209	5,188

Replacement of the existing dry scrubbers with modern new scrubbers could cost-effectively reduce facility SO₂ emissions by over 10,000 tons/yr.

– Time Necessary for Compliance (Statutory Factor 2)

NDDEQ: A summary of the anticipated timelines for the installation of the technically feasible control technologies is provided in Table 10.

Table 11. (NDDEQ draft SIP Table 10) Time Required for SO₂ Controls

Control Technology	Total time after SIP approval (months)
Station Work Practice	3
Ca:S Stoichiometry	51
DFGD (CDS/FF)	56
WFGD	60

The anticipated timelines for the installation of each of the control technologies indicates all options could be installed prior to the end of the second planning period.

– Energy and Non-Air Quality Environmental Impacts (Statutory Factor 3)

ENERGY

NDDEQ: The replacement of the existing drying scrubbing system with a CDS/FF or WFGD would increase the pressure drop through the control systems, which will increase the auxiliary power requirements. This would adversely affect the net plant heat rate. This impact is significant but not significant enough to eliminate either CDS/FF or WFGD as a control option.

NPS: This is an economic issue addressed under statutory factor 1, cost of compliance.

NON-AIR QUALITY ENVIRONMENTAL IMPACTS

NDDEQ: The installation and operation of a WFGD control option would generate a liquid calcium sulfate by-product that would need to be dewatered prior to disposal. In addition, WFGD control systems generate wastewater streams that typically contain a saturated solution of calcium sulfate, calcium sulfite, sodium chloride, trace amounts of fly ash, and unreacted limestone. The wastewater stream would need to be treated prior to discharge. WFGD systems also require significantly more water than dry systems. The non-air quality environmental impacts for WFGD are significant but not significant enough to eliminate WFGD as a control option.

NPS: The impacts raised are standard to the operation of WFGD.

– Remaining Useful Life (Statutory Factor 4)

NDDEQ: Based on the information provided to the Department, AVS is expected to operate beyond the life of the control equipment. Therefore, remaining useful life was not considered.

NO_x Emission Controls

SELECTIVE NON-CATALYTIC REDUCTION (SNCR)

Selective non-catalytic reduction (SNCR) involves the direct injection of ammonia or urea (CO(NH₂)₂) at high flue gas temperatures (approximately 1,600°F – 2,100°F) in an oxidizing environment. The ammonia or urea reacts with NO_x in the flue gas to produce N₂ and water as shown below.

NDDEQ: Installation of SNCR post combustion add-on control equipment has a limited impact on removing NO_x emissions from the flue gas. The limited removal is due to low NO_x concentrations in the flue gas stream affecting the reaction kinetics. Sources that are well suited for SNCR typically have an uncontrolled NO_x concentration above 200 ppm. AVS is generally around 60 ppm uncontrolled NO_x, making AVS not well suited for SNCR application. SNCR is anticipated to provide an approximately 18% reduction in NO_x emissions from the baseline scenario, lowering the expected performance rate from

0.11 to 0.09 lb NO_x per MMBtu. SNCR has a limited impact on reducing NO_x, however, installation of

SNCR on Unit 1 and Unit 2 at AVS is technically feasible and will be evaluated further.

SELECTIVE CATALYTIC REDUCTION (SCR)

S&L for AVS: SCR is a process by which ammonia (NH₃) reacts with nitric oxide (NO) and nitrogen dioxide (NO₂), collectively NO_x, in the presence of a catalyst to reduce the NO_x to nitrogen (N₂) and water (H₂O). SCR technology has been applied to NO_x-bearing flue gases generated from power generating facilities burning various types of coal, including bituminous, subbituminous, and Texas lignite. The principal reactions resulting in NO_x reduction are:

Because these reactions proceed slowly at typical boiler exit gas temperatures of a coal-fired steam -electric generating unit, a catalyst is used to increase the reaction rate between NO_x and NH₃. Depending on the specific constituents in the flue gas, a typical temperature range of 550°F to 780°F is necessary to achieve normal performance of the catalyst. For the typical coal-fired boiler, optimal performance will be in the range of approximately 650°F to 750°F.

In the tail-end configuration, the SCR reaction vessel is located in the flue gas stream after the particulate and FGD control systems. The potential advantage of a tail-end SCR configuration at Coyote Unit 1 is that the flue gas will have passed through the dry FGD/FF system prior to the SCR catalyst. As such, there is the possibility that the mass transfer mechanism that results in the capture of SO₂ will also capture some of the vapor-phase sodium and the sodium-enriched submicron particles, reducing the risk of catalyst poisoning and/or deactivation.

Successful operation of the tail-end configuration would also require a capital and operating cost-intensive gas-to-gas heat exchanger to reheat the flue gas from approximately 170 °F downstream of the existing fabric filter to approximately 550°F to support the SCR NO_x reactions. After the flue gas passes through the SCR (at approximately 550°F), it would pass through the hot side of the gas-to-gas heat exchanger to cool the flue gas to 150°F prior to the exhaust stack. Although this stack gas temperature would be lower than the current stack temperature (165-170°F), it is still higher than the adiabatic saturation temperature of the flue gas (i.e., approximately 135°F). As such, it is likely that the existing stack could be reused with minor modifications.

NDDEQ: During the first regional haze program planning period in North Dakota, the Department determined that installation of SCR, in any configuration, is not a technically feasible control technology since it has not been demonstrated in practice on North Dakota lignite coal. However, the earlier determination focused on cyclone-fired boilers. Successful use of TE-SCR controls have since been demonstrated at existing bituminous- and subbituminous-fired units. Therefore, the current determination is deeming TE-SCR as being technically feasible. TE-SCR is anticipated to provide an approximately 55% reduction in NO_x emissions from the baseline scenario, lowering the expected performance rate from 0.11 to 0.05 lb NO_x per MMBtu. TE-SCR is assumed technically feasible for installation on Unit 1 and Unit 2 at AVS and will be evaluated further.

NPS: Tail-End SCR should be able to reduce NO_x emissions by at least 60% and achieve 0.04 lb/mmBtu at AVS. For example, EPA assumed in 2014 that SCR could achieve the 0.04 lb/mmBtu annual emissions proposed by Basin at its Laramie River Station in WY. 2020 CAMD data contains 11 coal-fired EGUs with SCR at 0.04 lb/mmBtu annual average.

– Cost of Compliance (Statutory Factor 1)

S&L for AVS : Capital costs and lost revenues were annualized using a capital recovery factor based on an annual interest rate of 5.25% and equipment life of 20 years.

NPS: The CCM recommends use of the current prime interest rate of 3.25% over a 30-year life.

S&L for AVS: The AVS Units 1 and 2 cost estimates are conceptual in nature; thus, S&L did not procure equipment quotes specifically for the Units 1 and 2 control system upgrades. Rather, equipment costs are based on conceptual designs developed for the retrofit control systems, preliminary equipment sizing developed for the major pieces of equipment (based on AVS-specific design parameters, including typical fuel characteristics, full load heat input, and flue gas temperatures and flow rates), and recent pricing for similar equipment. S&L would characterize the cost estimates for the AVS Units 1 and 2 retrofit technologies as “concept screening” cost estimates generally based on parametric models, judgment, or analogy.

Control technology equipment costs for the retrofit options were developed by scaling cost estimates prepared by S&L for other similar projects. Major equipment costs were developed based on equipment costs recently developed for similar projects, and include the equipment, material, labor, and all other direct costs needed to retrofit the units with the control technology. Sub-accounts for the capital cost estimates (e.g., mobilization and demobilization, consumables,

Contractor G&A expense, freight on materials, etc.) were developed by applying ratios from detailed cost estimates that were prepared for projects with similar scopes.

Fixed O&M costs include operating labor, maintenance labor, maintenance material, and administrative labor. Variable O&M costs include the cost of consumables, including reagent, water consumption, and auxiliary power requirements. Auxiliary power requirements reflect the additional power requirements associated with the operation of the new control technology (compared to the existing technology). All O&M costs reflect the incremental increase in O&M costs compared to the costs incurred to operate the existing control systems.

NPS: Instead of using CCM cost models the four-factor analysis used an outdated methodology that includes owners costs as well as property taxes and an unjustified contingency cost. Inclusion of owners costs is not allowed by EPA and ND does not assess property taxes. We analyzed costs according to the CCM and provide results in Tables 12 and 13 below.

Table 12. NPS Revised, NDDEQ draft SIP Table 6: NO_x Cost of Compliance and Incremental Cost of Compliance for AVS Unit1

Control Technology	Performance Rate (lb/MMBtu)	Annual Emission Reduction (tpy)	Annualized Total Cost (\$)	Cost of Compliance (\$/ton)	Incremental Cost of Compliance (\$/ton)
SOFA/LNCFS	0.11				
(Baseline)					
SNCR	0.09	350	2,333,250	6,673	
TE-SCR	0.04	1,200	9,866,596	8,225	8,864

Table 13. NPS Revised NDDEQ Table 6: NO_x Cost of Compliance and Incremental Cost of Compliance for AVS Unit2

Control Technology	Performance Rate (lb/MMBtu)	Annual Emission Reduction (tpy)	Annualized Total Cost (\$)	Cost of Compliance (\$/ton)	Incremental Cost of Compliance (\$/ton)
SOFA/LNCFS	0.11				
(Baseline)					
SNCR	0.09	345	2,394,353	6,939	
TE-SCR	0.04	1,151	10,303,449	8,955	9,818

Addition of SNCR could reduce facility NO_x emissions by 700 ton/yr while addition of SCR could reduce facility NO_x emissions by over 2,300 tons/yr.

– Time Necessary for Compliance (Statutory Factor 2)

NDDEQ: A summary of the anticipated timelines for the installation of SNCR and TE-SCR is provided in Table 7.

Table 14. (NDDEQ draft SIP Table 7) Time Required for NO_x Controls

Control Technology	Total time after SIP approval (months)
SNCR	22
TE-SCR	52

The anticipated timelines for the installation of SNCR and TE-SCR indicate either option could be installed prior to the end of the second planning period.

– Energy and Non-Air Quality Environmental Impacts (Statutory Factor 3)

ENERGY

NDDEQ: The installation and operation of a TE-SCR would increase the pressure drop through the control systems, which would increase the auxiliary power requirements. This would adversely affect the net plant heat rate. This impact is significant but not significant enough to eliminate TE-SCR as a control option.

NON-AIR QUALITY ENVIRONMENTAL IMPACTS

NDDEQ: The installation and operation of the TE-SCR could result in an increase in sulfur emissions due to the potential oxidation of SO₂ to SO₃ and the subsequent reaction with moisture in the stack to form H₂SO₄.

NPS: This is not likely to be a problem with low-sulfur fuels.

NDDEQ: Both TE-SCR and SNCR use ammonia as a reagent. Ammonia slip emissions will result in the flue gas stream on the exhaust side of the control equipment due to the operation of TE-SCR (~2 ppm) and SNCR (~10 ppm). The ammonia slip emissions from the operation of SNCR would likely combine with the dry FGD solids. The ammoniated dry FGD solids would require that further safety precautions are taken for AVS staff who perform maintenance on the ash handling system or staff who dispose of waste. Ammonia slip emissions from the operation of the TE-SCR would be emitted to the atmosphere. Subsequently, the ammonia could combine with SOX and NO_x to form sulfates and nitrates, which will affect visibility.

The non-air quality environmental impacts for TE-SCR and SNCR are significant but not significant enough to eliminate either of them as a control option.

NPS: None of these impacts are unusual.

– Remaining Useful Life (Statutory Factor 4)

Based on the information provided to the Department, AVS is expected to operate beyond the life of the control equipment. Therefore, remaining useful life was not considered.

3.2.5 Conclusions & Recommendations

- Other states have set cost-effectiveness thresholds of: \$5,000/ton for EGUs in AR and TX, \$7,000/ton in NM, and \$10,000/ton in CO and OR.
- The incremental cost effectiveness of replacing the old scrubbers at AVS would be acceptable in the context of the previous ND BART thresholds as well as the thresholds used by the states cited. Replacement of the existing dry scrubbers with modern new scrubbers could cost-effectively reduce facility SO₂ emissions by over 10,000 tons/yr.
- The annual average cost effectiveness of adding SNCR at AVS would be acceptable in the context of the thresholds used by CO, NM, and OR. Addition of SNCR could reduce facility NO_x emissions by 700 tons/yr.
- The annual average cost effectiveness of adding SCR at AVS would be acceptable in the context of the thresholds used by CO and OR. Addition of SCR could reduce facility NO_x emissions by over 2,300 tons/yr.

3.3 Coal Creek

3.3.1 Summary of NPS Recommendations and Requests for Coal Creek Station

NPS review of the four-factor analysis conducted for Coal Creek Station (CCS) finds that there are technically feasible and cost-effective opportunities available to further control SO₂ and NO_x emissions from Units 1 and 2. In fact, we find that the cost of control is more economical than estimated when analyses are adjusted in accordance with the EPA Cost Control Manual.

Although ND has not established a cost threshold for this round of regional haze planning, we can advise that other states have set cost-effectiveness thresholds of: \$5,000/ton for EGUs in AR and TX, \$7,000/ton in NM, and \$10,000/ton in CO and OR.

The cost effectiveness of minimizing flue gas bypass to reduce SO₂ emissions at CCS would be acceptable in the context of the previous ND BART thresholds as well as the thresholds used by other states in this planning period. This control could cost-effectively reduce facility SO₂ emissions by almost 1,400 tons/yr.

We find SNCR and SCR opportunities for reducing NO_x emissions at CCS. 1) Addition of SNCR would be cost effective in the context of the previous ND BART thresholds as well as the thresholds used by other states in this round of RH SIP planning. SNCR at CCS Units 1 and 2 and could reduce facility NO_x emissions by almost 1,200 tons/yr. 2) The incremental cost effectiveness of adding SCR at CCS would be acceptable in the context of the previous threshold used by ND. Addition of SCR could reduce facility NO_x emissions by over 4,200 tons/yr.

CCS may also be able to reduce its substantial mercury emissions (ranked #1 in the country) by choosing to implement SCR ahead of the ESP or wet scrubbers. We encourage NDDEQ to evaluate this potential and weigh the co-benefits of mercury emission reduction when considering NO_x controls for CCS. This can be considered in reasonable progress analyses as part of statutory factor 3 (energy and non-air quality environmental impacts).

We recommend that ND take every opportunity to reduce SO₂ and NO_x emissions from the Coal Creek Station in this planning period. By requiring implementation of identified controls ND will be reducing haze causing emissions and advancing incremental improvement of visibility at Theodore Roosevelt, Badlands, and Wind Cave National Parks as well as other Class I areas in the region.

3.3.2 Coal Creek Station Plant Characteristics

Coal Creek Station (CCS) is a 1,210 MW mine-mouth lignite coal-fired power station owned and operated by Great River Energy (GRE) near Underwood, North Dakota. Theodore Roosevelt National Park, a Class I area administered by the National Park Service (NPS), is 159 km west of this facility.

Of 1,167 facilities in EPA's Clean Air Markets Database (CAMD) in 2020, CCS ranked #42 for sulfur dioxide (SO₂) emissions (5,301 tons) and #22 for nitrogen oxides (NO_x at 6,263 tons). CCS' carbon dioxide emissions of 9,543,317 tons rank #19 in the US. CCS also ranked #1 for EGU mercury (Hg) emissions with 314 lb in 2017.

Unit 1 and Unit 2 are identical subcritical 605 MW Combustion Engineering boilers firing pulverized lignite coal tangentially. Unit 1 began commercial operation in 1979 and Unit 2 began commercial operation in 1980. CCS receives lignite coal from the Falkirk Mine that is operated by the Falkirk Mining Company, a subsidiary of the North American Coal Corporation.

The existing NO_x control equipment for both Unit 1 and Unit 2 is LNC3+. LNC3+ is a combination of closed coupled overfired air, separated overfired air, and low NO_x burners (LNC3) in conjunction with DryFinishingTM and expanded overfire air registers (the "+" in LNC3+). LNC3+ was operational on Unit 2 in 2010 and on Unit 1 in the second quarter of 2020. Each unit is equipped with wet flue gas desulfurization (FGD) for SO₂ control and an electrostatic precipitator (ESP) for particulate control. Each unit employs halide injection and activated carbon injection for the control of mercury.¹⁶ Table 15 below shows a breakdown of 2020 SO₂ and NO_x emissions and how they rank versus the 3,317 EGUs in CAMD.

Table 15. CCS 2020 SO₂ and NO_x emissions and rank versus the 3,317 EGUs in CAMD

Unit ID	SO ₂ (tons)	SO ₂ (tons) Rank	Avg. SO ₂ Rate (lb/MMBtu)	Avg. SO ₂ Rate (lb/MMBtu) Rank	NO _x (tons)	NO _x (tons) Rank	Avg. NO _x Rate (lb/MMBtu)	Avg. NO _x Rate (lb/MMBtu) Rank
1	2,499	85	0.122	257	3,277	29	0.1630	396
2	2,801	75	0.120	260	2,986	40	0.1272	581

¹⁶ January 2021 Hg emissions were: Unit 1 = 3.79 lb/Trillion Btu (TBtu), Unit 2 = 3.82 lb/TBtu.

3.3.3 First Planning Period Regional Haze Control Requirements for CCS Units 1 and 2

CCS units 1 and 2 were subject to Best Available Retrofit Technology (BART) requirements. The first proposed regional haze SIP amendment was submitted by North Dakota to EPA Region 8 in March 2010. This SIP amendment was initially deemed complete by the EPA, Region 8 in April 2010. However, during the EPA's review, errors were discovered in the submission, which were specific to the Great River Energy's CCS BART analysis for NO_x emissions. In June 2012, North Dakota received a revised NO_x BART analysis from CCS which addressed the errors raised by the EPA. In January 2013, North Dakota submitted "Supplement No. 2" to EPA which addressed errors in the NO_x BART analysis for CCS.

"Supplement No. 2" provided updated and corrected information to the NO_x BART analysis but did not change the original BART determination. In the spring of 2018, the EPA concurred with North Dakota and proceeded with the required public comment period prior to making a final determination on NDDEQ's (the Department's) NO_x BART determination, including the Department's submitted "Supplement No. 2". EPA received comments on North Dakota's proposed BART determination, which were deemed to have merit. The EPA decided not to proceed with final approval of the Department's BART determination until the comments were adequately addressed. Since the EPA's decision to not proceed with a final approval, North Dakota, EPA Region 8, and CCS have been engaged to resolve the issues raised by the commenters and provide an updated BART determination.

CCS Units 1 and 2 are identical tangentially-fired pulverized coal boilers combusting North Dakota lignite coal. The existing NO_x controls were determined to be BART for Unit 1 and Unit 2 at CCS. The BART limit determined by the Department for each unit is a limit of 0.15 pounds per million Btu of heat input on a 30-day rolling average basis. This is lower than the proposed BART limit of 0.17 pounds per million Btu included in the "Supplemental No. 2" update provided in January 2013. The limit is to be achieved using the existing LNC3+ controls.

Supporting factors for NDDEQ's BART determination are: LNC3+ is cost feasible at \$700 per ton of NO_x reduced while providing a 28% reduction from the baseline emissions rate, and LNC3+ has negligible energy and non-air quality environmental impacts. Cost, technical feasibility concerns, added non-air quality environmental impacts, and limited modeled visibility improvement were the key factors in eliminating the consideration of add-on SNCR or SCR. The charts below show SO₂ and NO_x emissions for the CCS units.

Figure 8. CCS Unit 1, Calculated Avg. SO₂ Rate (1980–2020)

Figure 9. CCS Unit 1, Calculated Avg. NO_x Rate (1995–2020)

Figure 10. CCS Unit 2, Calculated Avg. SO₂ Rate (1980–2020)

Figure 11. CCS Unit 2, Calculated Avg. NO_x Rate (1996–2020)

3.3.4 Second Planning Period BART/Reasonable Progress Requirements for CCS Units 1 and 2

NDDEQ: The Department sent a letter to GRE on May 2, 2018 requesting a four factors analysis for CCS. The letter required that GRE’s four factors analysis be submitted to the Department on or before January 31, 2019. The Department emailed GRE on December 18, 2018 to inform GRE that they should focus on completing an updated BART analysis for the first round of Regional Haze planning. On September 12, 2019, GRE submitted an updated BART analysis associated with the first round of Regional Haze planning.

SO₂ EMISSIONS HISTORY

NDDEQ: June 2017 through December 2018 was used to determine the SO₂ baseline emissions rate from CCS. This time period was chosen since it serves as the best representation of expected emissions and performance rate of the WFGD operations. The average emissions rate of 0.14 lb SO₂ per MMBtu is representative of future expected operations. This value is used as the starting point when determining the cost of compliance for the add-on controls.

NPS: According to Barr Engineering’s December 2019 report:

Subsequently, in 2017, GRE designed and implemented a novel stack flue gas reheat system, which increases the exhaust temperature in order to allow each unit to operate with a dry stack and with improved capture of the flue gas to the existing wet gas scrubber (i.e., reduced use of the scrubber bypass).

We reviewed SO₂ emissions data January 2018 through September 2021 and agree with NDDEQ that 0.14 lb/mmBtu is an appropriate baseline.

SO₂ Emissions Controls

Barr for CCS: As described in GRE’s CCS BART report, several wet scrubber modifications were assessed. These included the addition of a fifth scrubber module and expansion of the existing absorber towers to scrub all the flue gas. With the implementation of DryFining™, the flue gas volume was reduced such that the existing scrubber modules could handle 100% of the flue gas, notwithstanding that the current stacks are designed as dry stacks. Therefore, the fifth

absorber module and/or expanded absorber towers are no longer needed. Further, conducting a four-factor evaluation to replace the existing wet scrubber system with a new design for a possible incremental level of improved SO₂ performance will inherently result in unreasonable costs on absolute cost and average cost effectiveness bases.

NDDEQ: The reasonable progress controls that were identified for analysis for CCS Unit 1 and Unit 2 are listed in Table 4, along with their approximate annual control efficiency. All controls were deemed technically feasible.

Table 16. (NDDEQ draft SIP Table 4) CCS Units 1 and 2, SO₂ Controls Identified for Analysis

Control Technology	Approximate Annual Control Efficiency
Dry Sorbent Injection	50-70%
Spray Dry Absorption	70-90%
Natural Gas Reheat System	96%
New Wet Stack	96%

CCS currently utilizes a minor bypass in limited situations to maintain dry stack conditions. A natural gas reheat system or new wet stacks would theoretically remove the need for this bypass, maximizing the proportion of flue gas to the wet scrubber. Both methods were analyzed as potential options and result in the same control efficiency. The existing WFGD system currently achieves an annual average removal efficiency of approximately 94% to 95%. Dry sorbent injection and spray dry absorption would not provide improvement over CCS's existing SO₂ emissions control system and were not evaluated further.

– Cost of Compliance (Statutory Factor 1)

NPS: We reviewed Barr's cost estimates and note that the Capital Recovery Cost was based upon a 5.25% interest rate and 20-year life which resulted in a Capital Recovery Factor = 0.08368. Instead, the Control Cost Manual (CCM) recommends use of the current prime interest rate (3.25%) over 30 years which yields a CRF = 0.0527.

NEW WET STACK

NDDEQ: One control option that was analyzed was the replacement of the current stacks on Unit 1 and Unit 2. CCS Unit 1 and Unit 2 are both dry stacks, despite using a wet scrubber. Converting the existing stacks to a wet stack design is not possible and instead new wet stacks would need to be constructed and the current stacks would be abandoned and demolished. For the evaluation of a new wet stack, Hamon Custodis, Inc. provided an initial high-level concept to effectively replace the two existing stacks with a rough budget price. CCS has added to this price a high-level and conservatively low set of cost estimates to convert the Custodis cost to an appropriate diameter and to include foundations, duct work, and continuous emissions monitoring systems (CEMS). A new wet stack would result in an approximate 1,377 ton per year reduction of SO₂.

NATURAL GAS REHEAT SYSTEM

CCS Units 1 and 2 currently utilize a novel flue gas reheat system that can maintain a dry stack under most operating situations, while maximizing the proportion of flue gas to the wet scrubber. During low load and cold weather operation, the existing reheat system does not provide enough thermal energy to reheat the stack gas to a dry state. The existing reheat system adds approximately 11 MMBtu/hr, and CCS estimates that approximately 31.5 MMBtu/hr of additional energy would be required to maintain a dry stack under all operating conditions. WBI Energy provided a cost estimate for a new gas line, with the cost split between both units. Barr Engineering provided an estimate for the natural gas-fired duct burner system, with additional consideration for site-specific installation factors. The installation of a new natural gas reheat system would result in an approximate 1,377 ton per year reduction of SO₂.

NPS: We calculated capital costs using the CCM recommended 3.25% interest rate and 30-year life. The cost-effectiveness of the options evaluated is well within accepted values.

Table 17. NPS Revised NDDEQ Table 5: SO₂ Cost of Compliance and Incremental Cost of Compliance for CCS Units 1 and 2

Control Technology	Performance Rate (lb SO ₂ /MMBtu)	Annual Emission Reduction (tpy)	Annualized Total Cost (\$)	Cost of Compliance (\$/ton)
WFGD (Baseline)	0.14			
New Wet Stack	0.08	1,377	2,841,363	2,063
Natural Gas Reheat System	0.08	1,377	3,000,849	2,179

– Time Necessary for Compliance (Statutory Factor 2)

NDDEQ: Both the new wet stack and natural gas reheat system would require at least two to three years to engineer, permit, and install the equipment. Therefore, time necessary for compliance is not a limiting factor when determining additional reasonable controls. The anticipated timeline would allow for either option to be installed prior to the end of the second round of regional haze.

– Energy and Non-Air Quality Environmental Impacts (Statutory Factor 3)

NDDEQ: The replacement wet stack would result in the demolition and disposal of a significant amount of materials with associated use of demolition equipment and portable engines to accommodate these activities.

The natural gas-fired reheat system would result in additional non-SO₂ pollutant emissions from the combustion of natural gas onsite. Potential NO_x emissions are estimated to be between 14 and 27 tons per year.

The energy and non-air quality environmental impacts from the new wet stack or the natural gas reheat system are significant but not significant enough to remove the control technology from consideration.

NPS: Energy impacts are included in the cost analyses. There are no unusual environmental impacts.

– Remaining Useful Life (Statutory Factor 4)

NDDEQ: For the purposes of this analysis, a 20-year life was used for CCS to calculate emission reductions, amortized costs, and cost effectiveness. Therefore, remaining useful life does not need to be considered for the purposes of round 2 planning.

NPS: In the absence of a federally-enforceable constraint, we assumed a 30-year life.

3.3.5 NO_x BART analysis for Coal Creek Station Unit 1 and Unit 2

EXISTING NO_x CONTROLS

NDDEQ: The NO_x controls currently installed at CCS Units 1 and 2 consist of LNC3 (combination of closed coupled overfired air, separated overfired air, and low NO_x burners) is installed on Units 1 and 2. This technology is considered as part of the baseline emission calculation.

DryFiningTM technology has been installed and operating on Units 1 and 2 since 2010. DryFiningTM is an innovative technology developed by Great River Energy that reduces moisture and refines lignite coal. The technology increases the efficiency and performance of the fuel while reducing emissions. This technology is considered part of the baseline emissions. Units 1 and 2 have experienced approximately 0.02 lb NO_x/MMBtu of reductions since completion of DryFiningTM.

LNC3+ (LNC3 with expanded overfired air registers in conjunction with DryFiningTM) was installed on Unit 2 in 2007. Expanded overfired air was completed in 2007 with DryFiningTM coming online in 2010. Collectively, LNC3+ became fully operational on Unit 2 in 2010. Unit 1 had expanded overfired air registers installed in the second quarter of 2020. Unit 1's LNC3+ is expected to operate with a similar NO_x profile as the LNC3+ on Unit 2.

HISTORICAL AND FUTURE ANTICIPATED EMISSIONS

CCS installed LNC3+ on Unit 2 in 2010 and on Unit 1 in 2020 in advance of being required through an approved regional haze SIP amendment. Reducing NO_x emissions through combustion upgrades (e.g., LNC3+) in advance of installing add-on post combustion controls (e.g., SNCR or SCR) is always recommended as the first step. Fundamentally, it is better to produce less NO_x during the combustion process than it is to add-on post combustion pollution controls to remove NO_x after formation. This reduces the equipment size and the associated operational and maintenance costs of the add-on controls. CCS has already taken the step to install LNC3+ on both Units.

NO_x BART Determination for Unit 1 and Unit 2

The following determination was derived using combined average historical data for both units and using the data to make a single BART determination, which applies to both units. A single NO_x BART determination is made because Unit 1 and Unit 2 are identical boilers and have historically operated consistently.

– Step 1 – Identify All Available Retrofit Control Technologies

The BART controls that were evaluated for CCS are listed in Table 18 below (NDDEQ draft SIP table 6). Each control technology is listed along with its associated performance rate and total expected emissions on a yearly basis. Expected emissions were calculated using the performance rate, the potential heat input, and the annual capacity factor.

Table 18. (NDDEQ draft SIP Table 6) NO_x BART Control Options

Control Technology	Control Technology Abbreviation	Emission Rate (lb/MMBtu)	Emissions (tons/year)
low NO _x burners with closed coupled overfired air	LNC3 ^A	0.18	4,143 ^B
LNC3 with expanded overfired air registers in conjunction with DryFining™	LNC3+	0.13	2,980
selective non-catalytic reduction	SNCR	0.10	2,293
selective catalytic reduction	SCR	0.08-0.06	1,830-1,380

^A The emission rate for LNC3 includes the DryFining™ operation

^B 0.18 lb NO_x/MMBtu x 52.72x10⁶ MMBtu/yr x 0.87 / 2000 = 4,140 tons NO_x/year

NPS: Unit 1 had expanded overfired air registers installed in the second quarter of 2020. We evaluated 21 months of CAMD NO_x emissions data (January 2020–September 2021) and determined that the average emission rate was 0.146 lb/mmBtu (Figure 12).

Figure 12. CCS Unit #1 Calculated Monthly Avg. NO_x Rate (January 2020–September 2021)

Per EPA guidance, we used the last five years of NO_x emissions data for Unit 2 to determine an average emission rate of 0.129 lb/mmBtu. We use these values to estimate the cost-effectiveness of adding post-combustion NO_x controls.

– Step 2 – Evaluate Technically Feasible Control Technologies

NDDEQ: LNC3+ is technically feasible and is currently installed and operational on Unit 1 and Unit 2. LNC3+ was installed on Unit 2 in 2010 and was installed on Unit 1 in 2020.

SNCR is a type of post combustion add-on control equipment. SNCR is technically feasible for both units at CCS and was reviewed as a potential additional control option after LNC3+ installation.

SCR is a type of post combustion add-on control equipment. The technical feasibility of SCR is uncertain at CCS. SCR was reviewed as a potential additional control option after LNC3+ installation. SCR was evaluated based on two potential arrangements, including a “high-dust” and “low-dust” system. High-dust systems are located upstream of the particulate controls (electrostatic precipitator) and low-dust systems are located downstream of the particulate controls.

High-dust SCR systems have significant potential for catalyst surface plugging due to the high sodium concentrations in the lignite coal used at CCS. Additionally, without the completion of pilot testing, the SCR catalyst supplier was unable to ensure reliable performance and catalyst life given the significant uncertainty with potential plugging and catalyst deactivation.⁴ For these reasons, a high-dust SCR system is determined to be technically infeasible. This is consistent with the Department’s 2009 determination that high-dust SCR is not technically feasible for Units combusting North Dakota lignite coal.⁵

Low-dust SCR systems (including tail-end SCR) are located downstream of the electrostatic precipitator where most of the sodium-bearing fly ash particles are expected to be removed, potentially mitigating the issue of SCR catalyst plugging.⁶ The catalyst vendor, IBDEM Ceram, and the SNCR/SCR vendor, Fuel Tech, both expressed overall concerns with North Dakota lignite coal impacts on the SCR catalyst plugging and fouling. Both independently recommended pilot scale testing be completed to obtain actual performance data and determine catalyst impacts. Without consideration of the recommended pilot testing, a low-dust system potentially removes the concern with technical feasibility in relation to catalyst plugging. Therefore, a low-dust SCR system is determined to be technically feasible and is carried forward for further evaluation.

– Step 3 – Evaluate Control Effectiveness

NDDEQ: The efficiency of the BART controls, anticipated performance rates, and the projected emission reductions for each control option are listed in Table 7. The projected emissions reductions listed in Table 7 would occur at each unit (e.g. SNCR would reduce NO_x emissions by 1,850 tons per year from both Unit 1 and Unit 2, totaling 3,700 tons per year, beyond the baseline emissions).

Table 19. (NDDEQ draft SIP Table 7) Control Effectiveness and Emissions Reductions for CCS Units 1 and 2

Control Technology	Emission Rate (lb/MMBtu)	Control Efficiency	Emission Reduction (tons/year)
Baseline, LNC3 ¹	0.18	--	--
LNC3+	0.13	28%	1,163
SNCR	0.10	45%	1,850
SCR	0.08-0.06	56%-67%	2,310-2,770

¹ The emission rate for LNC3 includes the DryFinishingTM operation

Within the Updated BART Analysis, a range of performance rates for SCR were evaluated, which is why the information in Table 7 includes a range of options for SCR. The performance rates evaluated are consistent with currently available information for units operating SCRs. These anticipated performance rates ranged from 0.04 to 0.08 lb NO_x per MMBtu. The performance rate of 0.04 lb NO_x per MMBtu is not listed in Table 7 due to significant uncertainty that this rate could be achieved in practice and sustained for an extended timeframe. Therefore, the Department will not evaluate SCR at a performance rate of 0.04 lb NO_x per MMBtu for the purposes of this BART determination. Information presented throughout the remainder of this BART determination is specific to SCR at a performance rate of 0.06 and 0.08 lb NO_x per MMBtu.

NPS: For Selective Non-Catalytic Reduction (SNCR), we applied the relationship $y = 22.554x + 16.725$ from Figure 1.1c in the Control Cost Manual to estimate efficiency of 19% - 20%.

NPS: We estimate that Selective Catalytic Reduction (SCR) could achieve up to 69% - 73%% NO_x reduction down to 0.04 lb/mmBtu. (We note that Black & Veatch used this value in its September 4, 2019 Attachment A, Report “Best Available Retrofit Technology for NO_x Emissions from Coal Creek Unit 2 - 2019 Update.”) EPA assumed in 2014 that SCR could achieve the 0.04 lb/mmBtu annual emissions proposed by Basin at its Laramie River Station in WY. 2020 CAMD data contains 11 coal-fired EGUs with SCR at 0.04 lb/mmBtu annual average.

– Step 4 – Evaluate Impacts

Cost of Compliance (Statutory Factor 1)

NDDEQ: The cost of compliance and incremental cost for the BART controls are listed in Table 8 for a single unit. The incremental costs displayed in Table 8 were determined from LNC3+ to SNCR and from LNC3+ to SCR. The incremental cost between SNCR and SCR is not shown in Table 8 due to the high annualized cost difference in conjunction with a limited improvement in emissions reduction.

Table 20. (NDDEQ draft SIP Table 8) Cost of Compliance and Incremental Cost of Compliance for CCS Units 1 and 2

Control Technology	Performance Level (lb/MMBtu)	Annual Emission Reduction (tpy)	Annualized Total Cost (\$)	Cost of Compliance (\$/ton)	Incremental Cost of Compliance (\$/ton)
Baseline, LNC3	0.18	--	--	--	--
LNC3+	0.13	1,162	793,418	683	--
LNC3+ w/ SNCR	0.10	1,850	6,194,244	3,348	7,850
LNC3+ w/ SCR	0.08	2,309	16,122,491	6,983	13,368
LNC3+ w/ SCR	0.06	2,767	17,391,169	6,284	10,339
